Circuit lower bounds and linear codes

(preliminary version)

Ramamohan Paturi* Pavel Pudlák†

January 13, 2004

Abstract

In 1977 Valiant proposed a graph theoretical method for proving lower bounds on algebraic circuits with gates computing linear functions [5]. He used this method to reduce the problem of proving lower bounds on circuits with linear gates to to proving lower bounds on the rigidity of a matrix, a concept that he introduced in that paper. In 1990 J. Friedman proved a lower bound on the rigidity of the generator matrices of error correcting codes over finite fields [3]. He showed that the proof can be interpreted as a bound on a certain parameter defined for all linear spaces of finite dimension. In this note we define another parameter which can be used to prove lower bounds on circuits with linear gates. Our parameter may be larger than Friedman's and it seems incomparable with the rigidity, hence it may be easier to prove a lower bound using this concept.

1 Introduction

The problem of proving nontrivial lower bounds on the size of circuits is one of the most fundamental problems in theoretical computer science. Its simplest version—the problem of proving nonlinear lower bounds on the size of logarithmic depth circuits computing an explicitly given function—is still open. It is open not only for boolean circuits, but even for algebraic circuits with gates computing linear functions. This is in spite of the apparent simplicity of such circuits; for example, in case of the two element field the circuits use only the parity gate. In 1977 Valiant found a reduction of the

ISSN 1433-8092

latter problem to an algebraic-combinatorial problem about matrices [5]. He introduced the concept of the rigidity function of a matrix and proved that sufficiently large lower bounds on the rigidity of a matrix imply nonlinear lower bounds on the size of circuits with linear gates computing the linear transformation defined by the matrix. In spite of the considerable amount of work done on this problem, we still lack strong bounds on the rigidity of explicitly defined matrices. The largest lower bound was proved by Friedman in 1990 [3]; he used generator matrices of a good code. The bound is still far from what is needed for circuit lower bounds. Friedman observed that his proof gives a little more: it gives a lower bound on a natural parameter of linear codes. More recently, Alekhnovich studied a hypothesis that is related both to the rigidity of matrices and to linear codes [1].

The theory of error correcting (and other) codes is a field with a large body of results and most of these concern linear codes. It is a field that extensively studies relations between algebraic and combinatorial properties of linear spaces. Thus we think that the relations between circuit complexity and codes deserves more attention than it was given so far. Codes with large minimal distances were used in lower bounds for various types of circuits, but the connection with circuits with linear gates seems to be the most promising. Therefore we will propose another reduction in this paper. It is also based on the graph-theoretical transformation of Valiant, but our parameter seems to be incomparable to rigidity and sometimes it is larger than Friedman's. So it may be easier to prove lower bounds on the circuit size using this parameter.

2 Circuits with linear gates

Let F be a field. We consider circuits whose gates are functions of the form $ax + by$, for $a, b \in F$. In particular, the fan-in of all gates is 2. The size of a circuit is the number of gates, the depth is the length of the longest (oriented) path. Such a circuit computes a linear transformation $f : F^n \to F^m$. We shall assume that there are no constant inputs, hence f will always be homogeneous. If $m = 1$, the problem of the circuit size complexity is trivial, thus we always consider $m > 1$. If $n = m$, then there are linear transformations whose complexity is almost quadratic, however, no non-linear lower bound is known for an explicitly defined f. This problem is open even with the additional restriction that the depth of the circuit be $O(\log n)$. The well-known result of Valiant [5] is a reduction of the above problem (with the log-depth restriction) to proving lower bounds on the rigidity of explicitly

defined matrices. It is based on the following combinatorial lemma.

Lemma 1 ([5]) *Let r, δ, σ be positive integers with $\delta > 4\sigma$. Let G be a directed acyclic graph with at most $r \log_2 \delta / \log_2(\delta/4\sigma)$ edges and depth at most δ. Then there exists a set of at most r edges such that after removing these edges, G does not contain a path of length σ.*

We shall say that a vector $v \in F^n$ is *s-sparse,* if the number of nonzero elements of v (the weight of v) is at most s. Valiant's result can be stated as follows.

Theorem 2 *Let r, δ, σ be as above. Suppose a linear transformation defined by an $m \times n$ matrix M can be computed by a circuit with linear gates and with size at most $r \log_2 \delta / (2 \log_2(\delta/4\sigma))$ and depth at most δ. Then the matrix can be decomposed as follows.*

$$M = A + BC, \tag{1}$$

where B is an $m \times r$ matrix, C is an $r \times n$ matrix and the rows of matrices A and C are 2^σ-sparse.

The concept of rigidity was derived by forgetting part of the information contained in equation (1). Namely, one uses only the information that A has at most sn nonzero entries, where $s = 2^\sigma$, and that the matrix BC has rank at most r. The rigidity of a matrix M is the function that expresses the dependence of the sparsity on the rank:

$R_M(r) =_{df} \min\{R;\ \exists A \text{ a matrix with } R \text{ nonzero entries such that } \operatorname{rank}(M-A) \leq r\}$.

For the purpose of this paper it is better to consider the function that expresses the dependence of the rank on the sparsity. Furthermore, we shall assume a uniform bound on the sparsity of the rows, as in Theorem 2. So we define:

$r_M(s) =_{df} \min\{r;\ \exists A \text{ a matrix whose rows are } s\text{-sparse, and } \operatorname{rank}(M-A) = r\}$.

Suppose that M has fewer rows than columns. We can derive from (1) that the row space of M is contained in the sum of the row space of A and the row space of BC. Since A and C are sparse matrices, we get nontrivial information about the row space of M. We shall use this observation to define two more functions. As they depend only on the row space of the matrix, we shall define them for spaces instead of matrices. The first one

is based on the concept of strong rigidity of Friedman [3]. Let $V \subseteq F^n$, $1 \leq s \leq n$.

$$d(s,V) =_{df} \max\{\dim(V \cap U);\ U \subseteq F^n,\ \text{generated by } s\text{-sparse vectors},\ \dim U = \dim V\}.$$

Let $\langle M \rangle$ denote the row space of M. The above two functions are related as follows:

$$\operatorname{rank} M - d(s, \langle M \rangle) = \dim\langle M \rangle - d(s, \langle M \rangle) \leq r_M(s).$$

Thus upper bounds on $d(s, \langle M \rangle)$ imply lower bounds on the rigidity of M. This relation was actually used in [3].

We define another function:

$$D(s,V) =_{df} \min\{\dim U;\ V \subseteq U \subseteq F^n,\ U \text{ generated by } s\text{-sparse vectors}\}.$$

The next inequality also follows immediately from the definitions.

$$\dim V - d(s,V) \leq D(s,V) - \dim V.$$

However, we do not know any nontrivial inequality involving $r_M(s)$ and $D(s, \langle M \rangle)$.

We already know that the rigidity of a matrix M, hence also $d(s, \langle M \rangle)$ can be used to prove a lower bound on the size of circuits computing the transformation defined by M. The function D can be used in the same manner. We state explicitly this corollary of Theorem 2 below. Given a circuit C with n inputs, we shall say that a space $V \subseteq F^n$ is *generated* by the circuit C, if $V = \langle M \rangle$, where M is the matrix of the linear transformation computed by the circuit (in the standard basis).[1]

Corollary 3 *Let r, δ, σ be as above. Suppose a space V can be generated by a circuit of size at most $r \log_2 \delta/(2\log_2(\delta/4\sigma))$ and depth at most δ. Then*

$$D(2^\sigma, V) \leq \dim(V) + r.$$

In particular, for all constants $c_1, c_2, \varepsilon > 0$ there exists a constant c_3 such that if V can be generated by a circuit of size at most $c_1 n$ and depth at most $c_2 \log n$. Then

$$D(n^\varepsilon, V) \leq \dim(V) + \frac{c_3 n}{\log\log n}.$$

[1] We can also say that V is the space generated by the linear functions computed at the output gates of C, however, it is important to say in which basis these vectors are presented.

3 Some simple bounds

We shall start with an estimate on the maximal value of $D(s,V)$ for spaces of a given dimension k over GF_2. Similar bounds can be proven for other finite fields.

Proposition 4 *Suppose F is GF_2. Let $k, s \leq n$ be arbitrary positive integers. Then there exists a space V with $\dim V = k$ such that*

$$D(s,V) \geq \frac{kn}{k + s\log_2 n}.$$

In particular, if $k \to \infty$ and $s \log n = o(k)$, then $D(s,V) = n - o(n)$.

Proof. We shall use a counting argument. The number of all subspaces of F^n of dimension k is $\begin{bmatrix} n \\ k \end{bmatrix}$. We shall upper bound the number of all sets of s-sparse vectors of size d by n^{sd}. If every space of dimension k is contained in the space spanned by d linearly independent s-sparse vectors, then

$$\begin{bmatrix} d \\ k \end{bmatrix} n^{sd} \geq \begin{bmatrix} n \\ k \end{bmatrix}.$$

Hence,

$$n^{sd} \geq \frac{(2^n-1)\ldots(2^n-2^{k-1})}{(2^d-1)\ldots(2^d-2^{k-1})} \geq \left(2^{n-d}\right)^k.$$

Thus

$$sd\log_2 n \geq k(n-d),$$

which proves the proposition. ∎

Hence a random space V of dimension $n/2$ has $D(n^\varepsilon, V) = n - o(n)$, whereas every space of dimension $n/2$ which can be generated by linear size log depth circuit has only $D(n^\varepsilon, V) = n/2 + o(n)$. This estimate also shows that $D(s,V) - \dim V$ can be much larger than $\dim V - d(s,V)$. Indeed, let $s(n) = n^\epsilon$, $0 < \epsilon < 1$ a constant; choose $k(n)$ so that $k(n) = o(n)$ and $s(n)\log n = o(k)$. Then we still have spaces V such that $D(s,V) = n - o(n)$, but $\dim V - d(s,V) \leq \dim V = k(n) = o(n)$. By padding these spaces we can get spaces V such that $\dim V = \Omega(n)$, $D(s,V) - \dim V = \Omega(n)$, and $\dim V - d(s,V) = o(n)$.

We shall present two simple lower bounds. The first one follows from Friedman's result; we present it only for the sake of completeness. Again, we state it only for the two element field.

Proposition 5 *Suppose $F = GF_2$. Let C be a $[n, k, d]$ code (a binary linear code with length n, dimension k and minimal distance d), let $s \leq d/2$. Then*

$$D(s, C) \geq k + \frac{d}{2s} \log_2 \left(\frac{2sk}{d} \right).$$

Proof. Let T be the linear transformation defined by the matrix of D s-sparse vectors. The fact that they generate C can be equivalently stated as $C \subseteq T(F^D)$. Let $C' = T^{-1}(C)$. Then C' is a $[D, k', d']$ code with $k' \geq k$ and $d' \geq d/s$. According to the sphere-packing bound we have

$$2^{k'} \binom{D}{d/2s} \leq 2^D,$$

whence

$$D \geq k' + \log_2 \binom{D}{d/2s} \geq k + \log_2 \left(\left(\frac{k}{d/2s} \right)^{d/2s} \right) \geq k + \frac{d}{2s} \log_2 (\frac{2sk}{d}).$$

■

It is possible to improve this bound by using stronger upper bounds on the dimension of codes of a given minimal distance, but the gain is only marginal.

Proposition 6 *Let F be an arbitrary field. Let C be a code of length n whose dual code $C^\perp$ has minimal distance d. Then*

$$D(s, C) \geq d - 1 + \frac{n - d + 1}{s}.$$

In particular, if $C^\perp$ is an MDS code (i.e., $d = \dim C + 1$), we get

$$D(s, C) \geq \dim C + \frac{n - d + 1}{s}.$$

Proof. Let M be the parity check matrix of a code of the minimal distance d. Thus every $d - 1$ columns of M are linearly independent. Suppose that there are D s-sparse vectors whose span contains C; let N be the $D \times n$ matrix formed by these vectors. Then every $d - 1$ columns of N are also linearly independent. Take $\frac{n-d+1}{s}$ rows of N. Since they are s-sparse, there are $d - 1$ columns in which these rows have only zeros. The matrix formed by these columns has rank $d - 1$, hence it must have $d - 1 + \frac{n-d+1}{s}$ rows. ■

We do not know the best value of $D(s, C)$ for particular MDS codes such as the Reed-Solomon code. In general, we do not believe that linear rate and linear distance of a code or its dual alone imply a nonlinear bound on log-depth circuits. However, for some extreme values, for instance, for codes that beat the Gilbert-Varshamov bound we might get larger bounds.

4 Pseudorandom generators

Our inability to prove lower bounds, even for such restricted computational models as considered here, is frustrating. In a recent paper [1] Alekhnovich suggested that this difficulty can be viewed also positively. Razborov and Rudich [4] showed that if there are pseudorandom generators (with appropriate parameters), then it is not possible to base certain circuit lower bound proofs on simple properties of functions. Alekhnovich's idea is to turn it over and try to design new pseudorandom generators based on the assumption that certain circuit lower bounds are difficult. Our lower bound setting suggests a simple and natural construction that might be a pseudorandom generator.

Construction. The parameters are numbers n, k, D, s. The input data are two matrices over GF_2, an arbitrary $k \times D$ matrix A and a $D \times n$ matrix B each of whose rows has exactly s nonzero elements. The output is AB (the matrix product of A and B).

If $kD + D\lceil \log_2 \binom{n}{s} \rceil < kn$, then the function produces more output bits then is the number of bits needed to encode the input data. We conjecture that for parameters of the form stated in Proposition 7) below, if A and B are chosen uniformly, then the output is not computationally distinguishable from the uniform distribution on all $k \times n$ matrices, (i.e., it is a pseudorandom generator). The following is some basic supporting evidence. (Of course, no such statistical properties can be used to derive computational complexity.)

Proposition 7 *Let $0 < \alpha < \beta < 1$ and $0 < \varepsilon < 1/2$. Let $k = \lceil \alpha n \rceil$, $D = \lceil \beta n \rceil$ and s an odd number, $s = \lceil n^{\varepsilon} \rceil$. Then*

1. *AB has full rank with probability exponentially tending to 1;*
2. *the distribution of every fixed column of AB is exponentially close to the uniform distribution;*
3. *the distribution of every fixed row of AB is exponentially close to the uniform distribution.*

Proof. 1. The probability that A does not have full rank is bounded by $2^{-n} + 2^{-n+1} + \ldots + 2^{-n+k-1} < 2^{k-n}$. For B we need the following claim.

Claim. Every subspace of GF_2^n of dimension d contains at most $\binom{d+s-1}{s}$ vectors of weight s.

Proof of the Claim. Let S be the set of supports of vectors of weight s of a given space; they are s-element subsets of $[n]$. Construct a sequence $s_1, s_2, \ldots, s_e$ of elements of S and a sequence of nonempty subsets $X_1, X_2, \ldots, X_e \subseteq [n]$ as follows. $s_1 = X_1$ is an arbitrary element of S. s_{i+1} is an element of S such that s_{i+1} is not a subset of $X \cup \ldots \cup X_i$ and such that $s_{i+1} \setminus (X_1 \cup \ldots \cup X_i)$ has the minimal cardinality. Then we put $X_{i+1} = s_{i+1} \setminus (X_1 \cup \ldots \cup X_i)$. Since the vectors corresponding to $s_1, s_2, \ldots, s_e$ are linearly independent, this sequence has to stop with $e \leq d$. Then every $s \in S$ is a subset of $X_1 \cup \ldots \cup X_e$. More precisely, every $s \in S$ is of the form $t \cup X_{i_1} \cup \ldots \cup X_{i_r}$ for some $t \subseteq s_1$ and $1 < i_1 < \ldots < i_r \leq e$. Clearly, we get the largest possible number of sets of this form if $|X_2| = \ldots = |X_e| = 1$ and $e = d$, which is the bound of the Claim.

Now we can bound the probability that B does not have full rank by

$$\frac{\binom{s}{s}}{\binom{n}{s}} + \frac{\binom{s+1}{s}}{\binom{n}{s}} + \ldots \frac{\binom{s+k-1}{s}}{\binom{n}{s}} < k\frac{\binom{s+k-1}{s}}{\binom{n}{s}} < k\left(\frac{s+k-1}{n-s+1}\right)^s,$$

which is also exponentially small. Clearly, the product of two full rank matrices of dimensions $k \times D$ and $D \times n$, with $k \leq D \leq n$, is a full rank matrix too.

2. The probability that a given column in B contains only zeros is

$$(1 - \frac{s}{n})^D = \mathrm{e}^{D \ln(1-\frac{s}{n})} < \mathrm{e}^{-\frac{Ds}{n}} \approx \mathrm{e}^{-\beta n^\varepsilon}.$$

If A is random and B is fixed with the i-th column nonzero, then the i-th column of AB has the uniform distribution. Hence if both A and B are random, then the distribution of the i-th column is exponentially close to the uniform distribution.

3. The distribution of a fixed row is given as follows. Take random $\mathbf{h}_1, \cdots, \mathbf{h}_D \in \{0,1\}$ and random vectors $\mathbf{u}_1, \cdots, \mathbf{u}_D \in GF^n$ each having exactly s ones. Then the distribution is

$$\sum_{i=1}^{D} \mathbf{h}_i \mathbf{u}_i$$

We can view it as the result of the Markov process in which we start with the zero vector, and at each step we do nothing with probability 1/2, or add a random vector with exactly s ones with probability 1/2. Put differently, it is the result of D steps of a random walk on the n-dimensional Boolean cube which starts at the zero vector, and at each step with probability 1/2 we do not move and with probability 1/2 we move to a vertex in Hamming distance s, choosing such a vertex with uniform probability. Thus we need only to estimate the size of the second largest eigenvalue of the matrix of this process. The eigenvectors of this matrix are the same as the eigenvectors of the graph G_s on $\{0,1\}^n$ in which two vertices are connected iff their Hamming distance is exactly s. This graph is a Cayley graph on the additive group of the vector space GF_2^n, hence the eigenvectors are the characters of this group. It is well-known that they are

$$\chi_a(x) = (-1)^{x^\top a}, \text{ for } a \in GF_2^n.$$

We shall first estimate the eigenvalues of G_s. To compute the eigenvalue associated with χ_a, it suffices to consider the vertex $\bar{0}$ and its neighbors. The eigenvalue is

$$(\chi_a(\bar{0}))^{-1} \sum_{|x|=s} \chi_a(x) = (-1)^{x^\top a}.$$

The largest eigenvalue (associated with $\chi_{\bar{0}}$) is the degree of the graph $\binom{n}{s}$. The second largest eigenvalue is at most $(1 - \frac{\gamma s}{n})\binom{n}{s}$, for a constant $\gamma > 0$ (We believe that it is precisely $(1 - \frac{s}{n})\binom{n}{s}$ and it is associated with all χ_a such that a contains exactly one 1, but the weaker statement is all that we need.) This follows from the lemma below.

Lemma 8 *Let s be an odd number $s = o(n)$ and $\emptyset \neq X \subseteq [n]$. Then the probability that the intersection of X with a random subset S of size s is odd is at least $\frac{\gamma s}{n}$ for a constant $\gamma > 0$ and provided that n is sufficiently large.*

Proof. Let us *fix* an S, $|S| = s$, s an odd number, and for $0 < k \leq n/2$, let let X be *a random set* of size k. Think of X as the result of the random process of choosing distinct elements $x_1, \cdots, x_n \in [n]$. Consider $|S \cap \{x_1, \cdots, x_{k-1}\}|$ and $|([n] \setminus S) \cap \{x_1, \cdots, x_{k-1}\}|$. The distribution of these random variables are sharply concentrated around the values $\frac{s(k-1)}{n}$, respectively $\frac{(n-s)(k-1)}{n}$. Hence the probability that $|S \setminus \{x_1, \cdots, x_{k-1}\}| \geq s/3$ and $|([n] \setminus S) \setminus \{x_1, \cdots, x_{k-1}\}| \geq n/3$ is bigger than some constant $\delta > 0$.

Suppose this event happens. If $|S \cap \{x_1, \cdots, x_{k-1}\}|$ is odd, then the probability that $|S \cap X|$ is odd is at least $1/3$. Otherwise the probability is at least $s/(3n)$. Thus the probability that $|S \cap X|$ is odd is at least $\delta s/(3n)$.

If $k > n/2$ think of X as the results of the random process of choosing distinct elements in its complement and then argue in the same way.

■

The matrix of the Markov process is

$$\frac{1}{2}\binom{n}{s}^{-1} A + \frac{1}{2} I,$$

where A is the adjacency matrix of G_s and I is the $2^n \times 2^n$ identity matrix. Hence the second largest eigenvalue of the Markov process is $1 - \frac{s}{2n}$. Thus the distance from the uniform distribution is bounded by $c^{D \cdot s/(2n)} \approx c^{\beta n^\epsilon/2}$, for some constant $c < 1$. ■

For sake of simplicity, we are using vectors with exactly s ones here instead of the vectors with at most s ones used before. We think that the difference is not essential (except that now we have to talk about s odd). Let us see what is the connection to lower bounds on the size of circuits. The conjecture about the generator can be restated as follows (we assume the same parameters as in Proposition 7).

> *A random k-dimensional subspace of a D-dimensional space generated by vectors with s ones is not computationally distinguishable from a random space of dimension k. We assume that the spaces are given by randomly chosen bases.*

Thus if we had a simple test that would distinguish the outputs of the generator from random spaces, then, probably, we could use this test to prove a lower bound.

Notice also that the spaces are described very compactly, so we may not be able to test properties such as the minimal distance. Hence the conjecture is more likely than if the spaces were given by the lists of all vectors. Therefore, it is also possible that the generator is a pseudorandom generator and still there exists a "natural" lower bound proof.
