Abstract. Quantified constraint satisfaction is the generalization of constraint satisfaction that allows for both universal and existential quantifiers over constrained variables, instead of just existential quantifiers. We study quantified constraint satisfaction problems CSP(Q, S), where Q denotes a pattern of quantifier alternation ending in exists or the set of all possible alternations of quantifiers, and S is a set of relations constraining the combinations of values that the variables may take. These problems belong to the corresponding level of the polynomial hierarchy or in PSPACE, depending on whether Q is a fixed pattern of quantifier alternation or the set of all possible alternations of quantifiers. We also introduce and study the quantified constraint satisfaction problems CSP'(Q, S) in which the universally quantified variables are restricted to range over given subsets of the domain. We first show that CSP(Q, S) and CSP'(Q, S) are polynomial-time equivalent to the problem of evaluating certain syntactically restricted monadic second-order formulas on finite structures. After this, we establish three broad sufficient conditions for polynomial-time solvability of CSP'(Q, S)that are based on closure functions; these results generalize and extend earlier results by other researchers about polynomial-time solvability of CSP(Q, S). Our study culminates with a dichotomy theorem for the complexity of list CSP'(Q,S), that is, CSP'(Q,S) where the relations of S include every subset of the domain of S. Specifically, list CSP'(Q, S) is either solvable in polynomial-time or complete for the corresponding level of the polynomial hierarchy, if Q is a fixed pattern of quantifier alternation (or PSPACE-complete if Q is the set of all possible alternations of quantifiers). The proofs are based on a more general unique sink property formulation.

### 1 Introduction

Constraint satisfaction problems are ubiquitous in several different areas of artificial intelligence and computer science, because constraints are widely used to specify design requirements (see [18]). Informally, an instance of a constraint-satisfaction problem consists of a set of variables, a set of possible values for the variables, and a set of constraints that restrict the combinations of values that certain tuples of variables may take; the question is to determine whether there is an assignment of values to the variables that satisfies the given constraints. As first articulated by Feder and Vardi [24], the CONSTRAINT SATISFACTION PROBLEM (CSP) can be formalized as the HOMOMORPHISM PROBLEM: given two finite relational structures A and S, is there a homomorphism h from A to S? A different, but equivalent, way to formalize CSP is to identify it with the CONJUNCTIVE QUERY EVALUATION PROBLEM: given a conjunctive query q and a finite relational structure S (that is, a relational database), does S satisfy q? Here, a *conjunctive query* is a first-order formula of the form  $\exists x_1 \ldots \exists x_m \psi$ , where  $\psi$  is a conjunction of atomic formulas with predicates from the vocabulary B of the structure S. Thus, CSP is also a fundamental problems in database query processing, since conjunctive queries (also known as *select-project-join* queries), are the most frequently asked queries in databases.

In its full generality, CSP is an NP-complete problem; for this reason, there has been an extensive pursuit of polynomial-time cases of CSP that are often called "islands of tractability" of constraint satisfaction (see [31, 17, 32, 29]). An instance of CSP consists of two parts: in the formulation of CSP as the HOMOMORPHISM **PROBLEM**, the two parts are a structure A and a structure S, while in the formulation of CSP as the CONJUNCTIVE QUERY EVALUATION PROBLEM the two parts are a conjunctive query q and a structure S. A parametrized family of constraint satisfaction problems CSP(S) can be obtained by fixing the structure S, where the input to each of these problems is a structure A in the first formulation, or a conjunctive query q in the second formulation. Much of the research on the complexity of CSP(S) is motivated from the *dichotomy conjecture* in [24], which asserts that for each structure S, the decision problem CSP(S) is either NP-complete or solvable in polynomial time. Schaefer's Dichotomy Theorem [33] for generalized satisfiability problems establishes this conjecture for Boolean structures, that is, when the universe of S is a two-element domain. More recently, Bulatov [4] established the dichotomy conjecture for structures S over a three element domain. This conjecture, however, remains open for structures with domains of cardinality bigger than three.

When formulated as the CONJUNCTIVE QUERY EVALUATION PROBLEM, constraint satisfaction can be viewed as an important special case of the MODEL CHECKING PROBLEM for first-order logic: given a first-order formula  $\varphi$  and a structure S, does S satisfy  $\varphi$ ? In turn, this suggests generalizing constraint satisfaction to quantified constraint satisfaction QCSP, as follows: given a first-order sentence of the form  $Q_1 x_1 \dots Q x_m \psi$  and a structure S, does S satisfy  $\psi$ ? Here, each  $Q_i$ is an existential or a universal quantifier, and  $\psi$  is a conjunction of atomic formulas with predicates from S. In other words, QCSP is the evaluation problem for positive disjunction-free first-order queries. Quantified constraint satisfaction is a PSPACE-complete problem and contains QSAT (also known as QBF) as a special case. As with CSP, one can obtain a parametrized family QCSP(S) of quantified constraint satisfaction problems by fixing the structure S. For Boolean structures S, this family contains Q3SAT as a member, one of the prototypical PSPACE-complete problems. The following dichotomy theorem for the complexity of Boolean QCSP(S) was established in [14, 13]: for every Boolean structure S, either QCSP(S) is PSPACE-complete or QCSP(S) is solvable in polynomial-time. More recently, researchers have embarked on a systematic investigation of the computational complexity of QCSP(S), where S is a structure over a finite domain [1,2,8]. Specifically, Börner et al. [1,2], using techniques from universal algebra,

found sufficient conditions for tractability of QCSP(S) that are based on closure functions. Furthermore, they obtained a trichotomy theorem for the complexity of QCSP(S), when the relations in S include all graphs of permutations: each such QCSP(S) problem is polynomial-time solvable, NP-complete or PSPACE-complete. Additional broad sufficient conditions for tractability of QCSP(S) based on closure functions were obtained by Chen and others [8–11].

In this paper, we extend the study of quantified constraint satisfaction in two different, but related, directions. First, we consider the class of problems CSP(Q, S), where Q is a pattern of quantifier alternation. Thus, standard constraint satisfaction CSP(S) coincides with  $CSP(\exists, S)$ , while QCSP(S) coincides with CSP(Q, S)where Q ranges over all possible patterns of quantifier alternation. Note that if the pattern Q has k alternation of quantifiers for some fixed integer k, then CSP(Q, S)belongs to the k-th level of the polynomial hierarchy PH. We also introduce the class of problems CSP'(Q, S) where universally quantified variables are required to vary over given subsets of the domain of S. One could also consider the extension CSP''(Q,S) of quantified constraint satisfaction where both universally quantified variables and existentially quantified variables are required to vary over given subsets of the domain of S. It turns out, however, that this extension is subsumed by the previous one, since it is easy to see that CSP''(Q, S) coincides with  $CSP'(Q, S \cup R)$  where R is the set of all subsets of the domain of S (that is, all possible unary constraints on the domain are present). Clearly, CSP'(Q, S) contains CSP(Q, S) as a subproblem. Consequently, tractability of CSP'(Q, S) implies tractability of CSP(Q, S), while C-hardness of CSP(Q, S) for a complexity class C implies C-hardness of CSP'(Q, S).

Our investigation of CSP(Q, S) and CSP'(Q, S) begins by showing that these problems are polynomial-time equivalent to the problem of evaluating certain syntactically restricted monadic second-order formulas on finite structures. After this, we establish three broad sufficient conditions for tractability of CSP'(Q, S) that are based on closure functions. Specifically, we show that CSP'(Q, S) (and, a fortiori, CSP(Q, S) is solvable in polynomial time if one of the following conditions holds: (1) all relations of S are closed under a *commutative-conservative* operation; (2) all relations of S are closed under a *near-unanimity* operation; (3) all relations of S are closed under a *Maltsev* operation. We also point out that CSP(Q, S) may be tractable, while at the same time CSP'(Q, S) may be intractable. Our study of the complexity of CSP'(Q, S) culminates with a dichotomy theorem for list CSP'(Q, S), that is, CSP'(Q, S) where the relations of S include every subset of the domain of S. Specifically, in this case CSP'(Q, S) is solvable in polynomial time or is complete for the k-th level of the polynomial hierarchy PH, if Q has k alternations of quantifiers (or is PSPACE-complete, if Q ranges over all patterns of quantifier alternation). The proofs are based on a more general unique sink property formulation. Finally, we obtain a dichotomy theorem for CSP'(Q, S) where the relations in S include all graphs of permutations.

## **2** $\operatorname{CSP}(Q, S)$ , $\operatorname{CSP}'(Q, S)$ , and $\operatorname{MMSNP}(Q, F)$

Let Q be an alternation of  $\forall$  and  $\exists$  quantifiers of length k ending in  $\exists$ , or let Q be the set of all possible alternations of quantifiers. We shall allow both of these

cases for Q unless otherwise indicated. We let  $C_Q$  be the complexity class  $\Sigma_k^P$  if k is odd, the complexity class  $\Pi_k^P$  if k is even (that is,  $C_Q$  is one of the levels of the polynomial hierarchy PH), and the complexity class PSPACE if Q consists of all possible alternations of quantifiers. In particular  $C_{\exists} = \Sigma_1^P = NP$  and  $C_{\forall \exists} = \Pi_2^P$ .

Let S be a fixed finite relational structure, that is,  $S = (V, R_1, \ldots, R_m)$  where V is a finite set and each  $R_i$  is a relation on V. An instance of CSP(Q, S) is a first-order sentence  $Q_1x_1 \ldots Q_lx_l(p_1 \land \ldots \land p_q)$ , where each  $p_i$  is an atomic formula involving one of the relations  $R_j$  from  $S, x_1, \ldots, x_l$  are the variables appearing in the  $p_i$ , and  $Q_1, \ldots, Q_l$  is a sequence of quantifiers with alternation pattern Q, that is, after identifying consecutive identical  $Q_i$  and possibly adding some additional quantifiers to the sequence of  $Q_i$ , we can obtain Q. The question is whether the structure S satisfies the sentence  $Q_1x_1 \ldots Q_lx_l(p_1 \land \ldots \land p_q)$ . We note that every problem CSP(Q, S) is in the complexity class  $C_Q$ .

An instance of  $\operatorname{CSP}'(Q, S)$  is defined similarly, except that in the first-order sentence, if  $Q_i$  is a  $\forall$  quantifier, we may use  $Q_i x_i \in S_i$  instead of  $Q_i x_i$ , where  $S_i$  is an arbitrary subset of the elements of S. More formally, an instance of  $\operatorname{CSP}'(Q, S)$ has two parts: the first part is a first-order sentence  $Q_1 x_1 \dots Q_l x_l (p_1 \wedge \dots \wedge p_q)$ , where each  $Q_i$  is the existential quantifier  $\exists$  or a bounded universal quantifier  $(\forall x_i \in S_i)$  for some unary relation symbol  $S_i$ ; the second part is a collection of subsets  $S'_{i_1}, \dots, S'_{i_r}$  of the universe V of S that interpret the unary relation symbols  $S_{i_1}, \dots, S_{i_r}$  occurring in the bounded universal quantifiers of the sentence. The question is whether the expanded structure  $S' = (V, R_1, \dots, R_m, S'_{i_1}, \dots, S'_{i_r})$ satisfies the sentence  $Q_1 x_1 \dots Q_l x_l (p_1 \wedge \dots \wedge p_q)$ . Again, every problem  $\operatorname{CSP}'(Q, S)$ is in the complexity class  $C_Q$ .

Every instance of CSP(Q, S) is also an instance of CSP'(Q, S), but not in the other direction. Indeed, an instance of CSP(Q, S) coincides with the instance of CSP'(Q, S) in which every unary relation symbol  $S_i$  in the bounded quantification  $(\forall x_i \in S_i)$  is interpreted by the universe V of S.

Feder and Vardi [24] studied the class of problems MMSNP, or monotone monadic strict NP without inequality. We study a more general class. Let Q be an alternation of quantifiers of length k ending in  $\exists$ . The problem MMSNP(Q, F)is defined by a second-order formula F with a second-order prefix that quantifies over monadic relations and has quantifier alternation Q as defined above, and a first-order universal part without the equality or inequality relations such that every input relation, not quantified in the second-order part, appears with negative polarity, that is, under the scope of an odd number of negations. An instance is a finite structure T having vocabulary given by the input relations in F, and the question is whether T satisfies F. Again, every problem MMSNP(Q, F) is in the complexity class  $C_Q$ . Feder and Vardi showed the following.

**Theorem 1.** [24] Every  $\text{CSP}(\exists, S)$  problem is an  $\text{MMSNP}(\exists, F)$  problem for some F dependent on S. For every  $\text{MMSNP}(\exists, F)$  problem, there exists a  $\text{CSP}(\exists, S)$  problem such that the  $\text{MMSNP}(\exists, F)$  problem reduces in polynomial time to the  $\text{CSP}(\exists, S)$  problem, and the  $\text{CSP}(\exists, S)$  problem reduces in randomized polynomial time to the  $\text{MMSNP}(\exists, F)$  problem.

We generalize the first statement of this theorem.

**Theorem 2.** For every CSP(Q, S) or CSP'(Q, S) problem, where Q is an alternation of quantifiers of length k ending in  $\exists$ , there exists a polynomial time equivalent MMSNP(Q, F) problem.

**Proof.** The input structure for the MMSNP(Q, F) problem is a given structure with relations of the same name and arity as S, plus additional monadic relations  $M_i$  to be added later.

For every quantifier type  $Q_i$  out of the k quantifier types in the alternation Qof length k and every element  $v_j$  in S, introduce a monadic relation  $R_{ij}$  which is quantified by  $Q_i$ . Require in the first-order part of F that for each existential  $Q_i$ and each variable x ranging over the input structure, exactly one  $R_{ij}(x)$  holds, for exactly one choice of j, giving the corresponding choice  $v_j$  in S for x ranging over the input structure. Also condition the first-order part for each universal  $Q_i$  and each x to choices of  $R_{ij}$  such that exactly one  $R_{ij}(x)$  holds, for exactly one choice of j, giving the corresponding choice of an element  $v_j$  in S for x ranging over the input structure.

For each quantifier type  $Q_i$  out of the k quantifier types in the alternation Q, add an input monadic relation  $M_i$ , and require that at most one  $M_i(x)$  hold for each element x, indicating that quantification  $Q_i$  has been chosen for x ranging over the input structure. Finally, for each relation A in S of arity r, require that if  $A(x_1, \ldots, x_r)$  holds and some corresponding  $M_i(x_i)$  holds, then  $A(v_1, \ldots, v_r)$ holds in S, where the  $v_j$  are given by the  $R_{ij}$  corresponding to the quantifier  $Q_i$ represented by  $M_i$ .

Thus a sentence  $Q_1 x_1 \ldots Q_l x_l (p_1 \land \ldots \land p_q)$  that gives an instance of CSP(Q, S) corresponds to an instance T of MMSNP(Q, F), where the structure T consists of the relations  $p_1, \ldots, p_q$  on its elements, and the relations  $M_i$  on its elements to indicate the chosen quantification  $Q_i$ . Conversely, an instance T of MMSNP(Q, F) gives such a formula, since we may assume that exactly only one  $M_i(x)$  holds by discarding elements that are not constrained by any  $M_i$ , since the formula is false when two  $M_i(x)$  hold for the same x.

The same holds for CSP'(Q, S) by adding for each subset S' of the elements of S a monadic relation  $M_{S'}$  such that  $\neg M_{S'}(x)$  indicates that x is restricted to S', and adding a disjunct to the first order part that holds when  $\neg M_{S'}(x)$  and the element  $v_i$  chosen for x with universal quantification  $Q_i$  is not in S'.

Courcelle's Theorem states that any problem in monadic second-order logic has a linear-time algorithm on instances of bounded treewidth [12, 19]. Thus for a fixed alternation of quantifiers Q of length k, all problems MMSNP(Q, F), and in particular problems CSP(Q, S) or CSP'(Q, S), have a linear-time algorithm on instances of bounded treewidth.

We may consider extensions of the class of all problems MMSNP(Q, F). A problem is MMSNP'(Q, F) if we also include the inequality relation as an input relation to an MMSNP(Q, F) problem. A problem is MMSNP''(Q, F) if it satisfies the requirements for MMSNP(Q, F) except for the condition that the formula be monotone in the input relations, so that input relations may appear with both positive and negative polarity. A problem is MMSNP''(Q, F) if it satisfies the requirements for MMSNP(Q, F) except for the last existential second-order quantifier in Q, which may quantify over binary relations as well. Feder and Vardi [24] conjectured that every problem  $MMSNP(\exists, F)$  is either polynomial time solvable or NP-complete, and showed that this conjecture fails for the three extensions of  $MMSNP(\exists, F)$ .

**Theorem 3.** [24] Every problem in NP has a polynomial time equivalent problem in each of the three classes of problems  $MMSNP'(\exists, F)$ ,  $MMSNP''(\exists, F)$  and  $MMSNP''(\exists, F)$ . In particular, if  $P \neq NP$ , these three classes contain problems that are neither in P nor NP-complete [30], and whether problems in each of these classes are polynomial or NP-complete is undecidable, even for problems guaranteed to be polynomial or NP-complete ahead of time.

We obtain a similar result and conjecture for a quantification Q.

**Theorem 4.** For a fixed alternation of quantifiers Q of length k ending in  $\exists$ , every problem in  $C_Q$  has a polynomial time equivalent problem in each of the three classes of problems MMSNP'(Q, F), MMSNP''(Q, F) and MMSNP''(Q, F).

**Proof.** As in [24] for MMSNP'( $\exists$ , F), we use the result of Hillebrand, Kanellakis, Mairson and Vardi [26] showing that monadic Datalog with inequality (but without negation) can verify a polynomial time encoding of a Turing machine computation. As in [24], the Turing machine may be assumed to be oblivious, and we may use existentially quantified monadic relations to guess nondeterministic inputs to the machine and the resulting states for the machine reaching an accepting state. With additional monadic relations quantified according to Q, we may allow for both nondeterministic existential and universal inputs to the machine, thus encoding a  $C_Q$  machine as an MMSNP'(Q, F) formula.

For MMSNP"(Q, F), as in [24], we may consider the MMSNP'(Q, F) encoding of a  $C_Q$  machine, and since the formula is now not required to be monotone, we may replace the occurrences of equality with a binary input relation eq. We require that eq be an equivalence relation (reflexive, symmetric, transitive). For all other input input relations and existential monadic relations are required to hold on some elements if and only if they hold on other elements related to these via the equivalence relation eq (for example, if M(x) and eq(x, y) then M(y) as well). Thus equality and inequality are simulated via eq and its negation, and therefore every  $C_Q$  machine is encoded as an MMSNP"(Q, F) formula.

For MMSNP<sup>'''</sup>(Q, F), as in [24], we include additional input and exsistential monadic and binary relations that force certain elements in the input structure to be marked and also force a uniquely defined existential binary equivalence relation eq on marked elements, so that the encoding of a  $C_Q$  machine as an MMSNP'(Q, F) formula yields an encoding as an MMSNP'''(Q, F) formula by representing inequality using eq.

**Conjecture 1.** For a fixed alternation of quantifiers Q, every problem MMSNP(Q, F) is either solvable in polynomial time or complete for some class  $\Sigma_k^P$  or  $\Pi_k^P$ .

## 3 The Graph of Closure Functions and the Unique Sink Property

Let f be a function of r arguments on the domain of S. We say that S is f-closed if for all relations R in S, of arity p, if  $R(a_{1j}, \ldots, a_{pj})$  holds in S for all  $1 \le j \le r$ , and  $f(a_{i1}, \ldots, a_{ir}) = b_i$  for all  $1 \le i \le p$ , then  $R(b_1, \ldots, b_p)$  also holds in S.

We shall consider problems such that if S is f-closed then f is *idempotent*, that is  $f(x, x, \ldots, x) = x$  for all x in S. We define the graph of closure functions of S to be a digraph G given as follows. The vertices of G are the elements of the domain of S. Given two distinct elements x, y in S, we include in G a directed edge (x, y)if S is f-closed for some f of some arity p such that for some choice of  $a_{ij} \in \{x, y\}$ for  $1 \le i, j \le p$ , we have  $a_{ii} = y$  for all  $1 \le i \le p$  and  $f(a_{i1}, \ldots, a_{ip}) = x$  for all  $1 \le i \le p$ .

We generalize the problems CSP(Q, S) and CSP'(Q, S) by defining the problem  $\text{CSP}^P(Q, S)$  for a collection P of subsets  $P_i$  of the domain of S. In  $\text{CSP}^P(Q, S)$  the universally quantified variables are only allowed to range over chosen subsets  $P_i$  from P. Thus CSP(Q, S) has P consisting only of the domain  $P_0$  of S, and CSP'(Q, S) has P consisting of all nonempty subsets  $P_i$  of P.

We say that a problem  $\text{CSP}^P(Q, S)$  has the unique sink property if S has G as the graph of its closure functions, and each subgraph  $G_i$  of G induced by a choice of  $P_i$  from P has a vertex  $v_i$  in  $P_i$  that is reachable from every vertex in  $G_i$ .

**Theorem 5.** Let Q be either a fixed alternation or an arbitrary alternation of quantifiers, and suppose  $\operatorname{CSP}^P(Q, S)$  has the unique sink property. then  $\operatorname{CSP}^P(Q, S)$  is polynomially equivalent to  $\operatorname{CSP}(\exists, S)$ , that is, these two problems reduce in polynomial time to each other. Thus  $\operatorname{CSP}^P(Q, S)$  is in NP (possibly polynomial or NP-complete).

**Proof.** Clearly  $CSP(\exists, S)$  reduces to  $CSP^{P}(Q, S)$ , so we reduce  $CSP^{P}(Q, S)$  to  $CSP(\exists, S)$ . For each graph  $G_i$  corresponding to each  $P_i$  define an oriented tree  $T_i$  spanning  $G_i$ , rooted at  $v_i$ , and with the edges oriented towards the root  $v_i$ .

We would like to consider all possible values of universal quantifiers. However, we shall restrict attention to some specific choices of combinations of values for universal quantifiers. For the trees  $T_i$ , consider cosen subtrees  $U_i$  of  $T_i$  containing  $v_i$ . Then we consider assignments to universal variables such that if there are muniversal variables ranging over  $P_i$  and assigned a particular value x of  $P_i$  not in  $U_i$ , and the edge (x, y) in  $T_i$  was obtained from a closure function f of arity p, then m < p.

If we let  $U_i = T_i$ , then we are considering all combinations of assignments to universally quantified values as needed. But if we only let  $U_i = \{v_i\}$ , then we are only considering a polynomial number of assignments, since if the maximum arity of functions f used is p, the maximum size of  $P_i$  is q, and the number of sets  $P_i$  in P is r, then only a constant number pqr of universally quantified variables could be assigned values different from the special value  $v_i$ , giving at most  $n^{pqr}q^{pqr}$  possible assignments to universal variables. Thus this last case reduces to  $CSP(\exists, S)$  as a polynomial number of instances may be combined into a single instance. When combining instances for different assignments to universally quantified variables, we make sure that existentially quantified variables for different universal combinations are the same variable if the universally quantified variables preceeding them have the same assignments of values. This identification of existential variables in the multiple instances combined is needed as existential variables depend only on the values of preceeding universal variables.

We shall show that solving the problem with  $U_i = \{v_i\}$  as we indicated also solves the problem of  $U_i = T_i$ . For this purpose, we start with  $U_i = T_i$  and succesively remove some leaf from some  $U_i$ , until we get all  $U_i = \{v_i\}$ . Consider say the step where we remove x from  $U_1$  to obtain  $U'_1$ . We must then drop all assignments that assign value x to  $p' \ge p$  universal variables ranging over  $P_1$ , where p is the arity of the closure function f that gave the edge (x, y) in  $T_1$ . We show how to take care of the removal of an assignment with  $p' \ge p$  largest. Consider the first pvariables  $w_1, \ldots, w_p$  out of these p' variables assigned x, and consider the p substitutions that replace their values  $x, \ldots, x$  with  $a_{1j}, \ldots, a_{pj}$ , for each  $1 \le j \le p$ . These assignments each have  $a_{jj} = y$  and all  $a_{ij} \in \{x, y\}$ , thus reducing the number p' of occurrences of x to p' - 1 at least. From a solution for each of these p'derived assignments we may obtain a solution for  $x, \ldots, x$  as in the original assignment by componentwise applying f, since S is f-closed and f is idempotent, by the definition of f.

Repeatedly taking care of the assignments with largest  $p' \ge p$  will eventually guarantee p' < p as required. We must also make sure when performing this substitution by p solutions with smaller p' that the values of existentially quantified variables only depend on preceeding existentially quantified variables, so a similar substitution is performed for each other assignment to universal variables that assign x to  $w_i$  for some  $1 \le i \le p$ . If after removing this assignment with large  $p' \ge p$ the existential variables depend only on the universal variables preceeding them, then componentwise applying f to both universal and existential variables will preserve the property of having existential variables depending only on preceeding universal variables. Once all p' < p, we may substitute  $U_1$  with  $U'_1$  consisting of removing x from  $U_1$ . Thus overall, we successfully solve the problem for all  $U_i = T_i$ by solving the problem obtained when we reach all  $U_i = \{v_i\}$ , completing the proof.

The simplest problems having the unique sink property are the cases where the graph G of the closure functions contains a tournament, so that every pair of elements in the domain of S are joined by an edge in either or both directions. The following are examples of this.

A function f of two arguments is a commutative conservative binary operation on S if  $f(a,b) = f(b,a) \in \{a,b\}$  for all  $a, b \in S$ . We note that the Horn and dual-Horn cases are f-closed for such a function f. Bulatov and Jeavons [7] showed that if S is f-closed for such a function f, then  $CSP(\exists, S)$  can be solved in polynomial time.

A function g of  $r \ge 3$  arguments is a *near-unanimity operation* on S if for a choice of elements  $a_i$  in S for  $1 \le i \le r$  such that there exists an element a in S and some  $1 \le j \le r$  such that  $a_i = a$  for  $i \ne j$ , we have  $f(a_1, \ldots, a_r) = a$ . In the special case r = 3, the near-unanimity operation is called a *majority operation*. A special case of a majority operation is the *dual discriminator operation* defined by d(x, y, z) = y if y = z and d(x, y, z) = x otherwise. We note that the bijunctive case

is *d*-closed for the dual discriminator operation *d*. It is shown in [1, 2] that if *S* is *d*closed for the dual discriminator operation *d*, then CSP(Q, S) is in nondeterministic logarithmic space, and thus in polynomial time. It is shown in [24] that if *S* is *g*closed for a near-unanimity operation *g*, then  $\text{CSP}(\exists, S)$  can be solved in polynomial time.

A function h of three arguments is a coset operation on S if there exists a group operation on S such that  $h(x, y, z) = xy^{-1}z$ . We note that the affine case (the case of linear equations modulo p) is h-closed for a coset operation h. It is shown in [1, 2] that if S is h-closed for the coset operation of an Abelian group, then CSP(Q, S)can be solved in polynomial time. Without assuming the group to be abelian, it is shown in [24] that if S is h-closed for a coset operation h, then  $\text{CSP}(\exists, S)$  can be solved in polynomial time.

A function h of three arguments is a *Maltsev operation* on S if h(x, x, y) = h(y, x, x) = y for all elements x, y in S. It is shown in [3] that if S is h-closed for a Maltsev operation h, then  $CSP(\exists, S)$  can be solved in polynomial time. An example of a Maltsev operation is the *switching operation* given by s(x, x, y) = s(y, x, x) = y and s(x, y, z) = y otherwise.

The following results were obtained by Bulatov, Chen [1,8] and others for CSP(Q, S). Here we obtain immediate corollaries of Theorem refmain

**Corollary 1.** If Q consists of all or some alternations of quantifiers, and S is f-closed for an operation that is commutative conservative, near unanimity, coset, or Maltsev, then  $\text{CSP}^P(Q, S)$  is polynomial time solvable for all choices of P.

The preceeding corollary also applies to various forms of majority-minority operations, see e.g. Dalmau [16]. The most general result in this direction is a *k*-edge operation, which has recently been shown to be tractable by Idziak, Markovic, McKenzie, Valeriote, and Willard [27]. It is given as an operation g of arity k+1 that satisfies  $g(x, x, y, \ldots, y) = g(x, y, x, y, \ldots, y) = g(y, y, y, x, y, \ldots, y) = g(y, y, y, y, x, y, \ldots, y) =$  $<math>\ldots = g(y, y, y, \ldots, y, x) = y$  for all x, y. Clearly this operation gives the unique sink property and is thus polynomial with arbitrary alternations of quantifiers as well as shown here.

Let R be the set of all subsets of the domain of S. Bulatov [5] showed that if the monadic relations constituting R are in S, that is, the fixed structure Scontains all monadic relations, then  $\text{CSP}(\exists, S)$  is either polynomial time solvable or NP-complete.

**Theorem 6.** Let R be the set of all subsets of S, and suppose  $R \subseteq S$ . Then CSP'(Q, S) is either polynomial time solvable or  $C_Q$ -complete; The criterion distinguishing polynomial and  $C_Q$ -complete cases is the same as the criterion distinguishing polynomial and NP-complete cases for  $CSP'(\exists, S)$  in [5].

**Proof.** The NP-complete cases of  $CSP(\exists, S)$  in [5] simulate the one-in-three SAT relation  $T = \{001, 010, 100\}$  on two particular elements 0 and 1 in S, so  $C_Q$ -completeness for CSP'(Q, S) follows the known classification of the Boolean domain case [25]. The polynomial cases follow from Theorem 5 since the graph G contains a tournament.

The result of [5] for the case where all subsets appear as monadic relations in S has been generalized to the case where subsets of size at most three appear as monadic relations in S. The proof involves a similar G containing a tournament derived from [5], so the preceeding theorem carries over to this case as well. A similar conjecture when only subsets of size at most two are required to appear as constraints remains open. We may also conjecture polynomiality more generally whenever G contains a tournament.

When G does not contain a tournament, one can construct examples of S for which  $\text{CSP}(\exists, S)$  is instead NP-complete. For this it suffices to include only relations involving pairs of values x, y, and if the edge (x, y) is directed only in one direction only use Horn clauses on this pair of values, and when no edge joins x, y include the NP-complete one-in-three SAT problem on these two values. However CSP(Q, S)remains NP-complete if the unique sink property does hold. However if the unique sink property does not hold then CSP(Q, S) can go up in complexity as high as  $C_Q$ -complete.

A semilattice operation is a binary operation satisfying f(a, a) = a, f(a, b) = f(b, a), f(a, f(b, c)) = f(f(a, b), c). Bulatov and Chen [6] have shown that for the problem of f-closed structures for a semilattice operation f, then CSP(Q, S) and CSP'(Q, S) are polynomial if the unique sink property holds in either case, otherwise the problems are coNP-complete for any alternation of quantifiers involving at least one for-all (while still polynomial with just one exists), and for arbitrary alternations they become PSPACE-complete. It is easy to extend these results to  $\text{CSP}^P(Q, S)$  in the obvious manner.

#### 4 Trichotomies for Graphs of Permutations

Assume S contains at least three elements. Let  $\Delta$  be the set of all graphs of permutations on the elements of S, that is, the set of all binary relations  $\{(x, y) : y = \pi(x)\}$ for permutations  $\pi$ . Börner, Krokhin, Bulatov, and Jeavons [1, 2] classified the complexity of CSP(Q, S) in the cases where Q consists of all alternations of quantifiers and  $\Delta \subseteq S$ , obtaining a trichotomy as polynomial, NP-complete, or PSPACEcomplete. The polynomial cases remain polynomial if Q is a fixed alternation of quantifiers ending in  $\exists$ . The NP-complete cases are such that  $CSP(\exists, S)$  is also NP-complete, and thus remain NP-complete if Q is a fixed alternation of quantifiers ending in  $\exists$ . The PSPACE-complete cases are such that S is f-closed for a surjective function f if and only if f is a projection. Note if S is f-closed for a function f, then f must be surjective because S contains all graphs of permutations, so that if  $f(a_1,\ldots,a_k) = b$  then  $f(\pi(a_1),\ldots,\pi(a_k)) = \pi(b)$  for every permutation  $\pi$ . Thus the PSPACE-complete cases are such that S is f-closed for a function f (surjective or not) if and only if f is a projection. Thus by a result of Post (see also Jeavons [28]),  $CSP(\exists, S)$  simulates all relations, and in particular simulates the binary relation W of a complete irreflexive graph on the elements in S. The proof in [1] that  $CSP(Q, \{W\})$  is PSPACE-complete when Q consists of all alternations of quantifiers gives a reduction from  $CSP(Q, \{NAE\})$  for the not-all-equal relation NAE, which is PSPACE-complete by Theorem 6, and adapts to a proof that  $\text{CSP}(Q, \{W\})$  is  $C_Q$ -complete for a fixed alternation of quantifiers Q ending in  $\exists$  with a corresponding reduction from  $\text{CSP}(Q, \{\text{NAE}\})$  and Theorem 7. Thus the PSPACE-complete cases become  $C_Q$ -complete in this case. A similar proof can be found in [2]

**Theorem 7.** If W is an irreflexive clique on  $r \ge 3$  elements, then  $CSP(Q, \{W\})$  is  $C_Q$ -complete.

**Proof.** The proof that  $\text{CSP}(Q, \{W\})$  is  $C_Q$ -complete for a clique W of size  $r \geq 3$  encodes an instance of  $\text{CSP}(Q, \{\text{NAE}\})$  by making  $\binom{r}{2}$  copies of the variables  $v_i$  and constraints  $\text{NAE}(v_i, v_{i'}, v_{i''})$ , then replaces each universally quantified  $v_i$  in the resulting instance with two variables  $x_i, y_i$  with an edge  $(x_i, y_i)$ , each existentially quantified  $v_i$  with a variable  $y_i$ , and also replaces each constraint  $\text{NAE}(v_i, v_{i'}, v_{i''})$  with a triangle  $(t_i, t_{i'}, t_{i''})$  and edges  $(y_i, t_i), (y_{i'}, t_{i'}), (y_{i''}, t_{i''})$ . Finally, a clique  $(u_1, \ldots, u_{r-2})$  is added with edges joining the  $y_i$  to all  $u_j$  and edges joining the  $t_i$  to all  $u_j$  other than  $u_{r-2}$ . The quantification for the  $v_i$  is replicated as a universal quantification for the corresponding  $x_i$  or as an existential quantification for the corresponding  $y_i$ , followed by existential quantification on the  $y_i$  corresponding to universally quantified variables and on the  $t_i$  at the end of the formula, and with the first existential quantifiers applied to the  $u_j$ .

If we consider the  $\binom{r}{2}$  choices of pairs of possible values a, b for the first universally quantified  $x_i$  and use them in the  $\binom{r}{2}$  corresponding copies of the original instance, we may assume that variables  $u_1, \ldots, u_{r-2}$  do not take the two values a, b in one of these copies, in which case the variables  $y_i$  take values a, b, corresponding to values 0, 1 on the  $v_i$  that must satisfy the NAE constraints as required by the triangles of  $t_i$ . The cases where some  $x_i$  do not take values among a, b are more easily satisfied.

As argued above, Theorem 17 implies the following.

**Theorem 8.** Suppose S contains the set  $\Delta$  of all graphs of permutations. Then CSP(Q, S) is either polynomial, NP-complete, or  $C_Q$ -complete.

The polynomial cases in Theorem 18 are those that are closed under the dual discriminator d, or the switching operation s, or an affine operation, so these cases remain polynomial for CSP'(Q, S) as well by Theorems 9 and 11. The NP-complete cases in Theorem 18 are such that  $\text{CSP}(\exists, S)$  simulates the not-all-equal relation N on a 2-element subdomain [15], and so Theorems 6 and 7 imply that CSP'(Q, S) is  $C_Q$ -complete. The  $C_Q$ -complete cases in Theorem 18 remain  $C_Q$ -complete for CSP'(Q, S).

**Theorem 9.** Suppose S contains the set  $\Delta$  of all graphs of permutations. Then CSP'(Q, S) is either polynomial or  $C_Q$ -complete.
