Abstract

In this paper we will be concerned with a large class of packing and covering problems which includes Vertex Cover and Independent Set. Typically, for NP-hard problems among them, one can write an LP relaxation and then round the solution. For instance, for Vertex Cover one can obtain a 2-approximation via this approach. On the other hand, Khot and Regev [KR08] proved that, assuming the Unique Games Conjecture (UGC), it is NP-hard to approximate Vertex Cover to within a factor better than $2 - \epsilon$ for any constant $\epsilon > 0$. From their, and subsequent proofs of this result, it was not clear why this LP relaxation should be optimal.

The situation was akin to Maximum Cut, where a natural SDP relaxation for it was proved by Khot et al. [KKMO07] to be optimal assuming the UGC. A beautiful result of Raghavendra [Rag08] explains why the SDP is optimal (assuming the UGC). Moreover, his result generalizes to a large class of constraint satisfaction problems (CSPs). Unfortunately, we do not know how to extend his framework so that it applies for problems such as Vertex Cover where the constraints are strict.

In this paper, we explain why the simple LP-based rounding algorithm for the Vertex Cover problem is optimal assuming the UGC. Complementing Raghavendra’s result, our result generalizes to a larger class of strict, covering/packing type CSPs. We first write down a natural LP relaxation for this class of problems and present a simple rounding algorithm for it. The key ingredient, then, is a dictatorship test, which is parametrized by a rounding-gap example for this LP, whose completeness and soundness are the LP-value and the rounded value respectively.

To the best of our knowledge, ours is the first result which proves the optimality of LP-based rounding algorithms systematically.

1 Introduction

In this paper we will be interested in a fairly large class of packing and covering problems. We will show that, assuming the Unique Games Conjecture, a natural linear programming relaxation for such a problem, along with a simple rounding scheme, is the best one can hope for algorithmically. We start with a classic covering problem that falls in this class: the minimum vertex cover problem (Vertex Cover). The equivalent packing problem is the maximum independent set problem (Independent Set).

Vertex Cover. In the Vertex Cover problem, one is given a graph $G(V,E)$ with non-negative weights $\{w_e\}_{e \in E}$ for the vertices and the goal is to find a subset of minimum weight such that every edge has at least one end point in this set. We may assume that $\sum_{e \in E} w_e = 1$. This problem is NP-hard and there is a very simple 2-approximation algorithm known for it. One way to obtain this approximation, which will be relevant to our work, is to solve the following natural linear programming (LP) relaxation.

$$\text{lp}_{\text{vc}}(G) \overset{\text{def}}{=} \text{minimize} \quad \sum_{e \in E} w_e x_e$$

subject to \quad \forall_{e = uv \in E} \quad x_u + x_v \geq 1

\quad \forall_{v \in V} \quad x_v \geq 0

Figure 1: LP for Vertex Cover

Given an optimal solution to this LP, the rounding scheme selects vertices whose variables have value at least $\frac{1}{2}$. This makes sure that the picked set is a vertex cover and the cost is no more than twice $\text{lp}_{\text{vc}}(G)$.

On the inapproximability side, Dinur and Safra proved that Vertex Cover is NP-hard to approximate to within a factor of 1.36. Khot and Regev \cite{KhoRe08} gave some evidence that factor 2 might be the best possible approximation for Vertex Cover by showing that if there is an algorithm for Vertex Cover which achieves a factor better than 2, then the Unique Games Conjecture (UGC) is false. However, it is not clear from their hardness reduction why this simple minded LP is the best one.

One can think of Vertex Cover as a strict version of a constraint satisfaction problem (CSP). While in a CSP, the objective is to satisfy as many constraints as possible, in Vertex Cover, the objective is to find a solution satisfying all constraints while minimizing a different objective. Although the difference seems superficial, the algorithmic implications for the two class of problems are quite different. Let us take the example of Maximum Cut, the simplest and one of the most interesting CSP. Given a graph $G(V,E)$, the Maximum Cut problem asks for a partition $(S, \bar{S})$ of the vertices maximizing the number of edges going across the cut. For the Maximum Cut problem, the natural LP relaxation is known to give a strictly weaker approximation than a simple semidefinite programming (SDP) relaxation \cite{GraWag95}. Further, the factor obtained by the SDP is optimal assuming the UGC as was shown in Khot et al. \cite{KhoKaiMar07}. A beautiful result of Raghavendra \cite{Rag08} manages to generalize the Maximum Cut result of \cite{KhoKaiMar07} to a very general class of constraint satisfaction problems. In particular, he considers a generic way to write a SDP relaxation, and shows that the approximation ratio achieved by the SDP is optimal assuming the UGC.

However, Raghavendra’s result does not seem to apply for Vertex Cover even though it is possible to think of Vertex Cover as a CSP in the following way: consider an instance $G = (V,E)$ of Vertex Cover. We have boolean variables $x_v$ for each $v \in V$. For each vertex $v$, we have a constraint $\Phi_v(x_v)$ which is 1 if $x_v$ is 1 (which corresponds to vertex $v$ being picked in the vertex cover), and 0 otherwise. For each edge $e = uv$, we have a constraint $\Psi_e(x_u, x_v)$ which is 0 if at least one of $x_u$ or $x_v$ is 1, and 1 otherwise. The goal is to minimize the weighted sum $\sum_v w_v \Phi_v(x_v) + 2 \cdot \sum_{e \in E} (w_u + w_v) \cdot \Psi_e(x_u, x_v)$. It is easy to argue that any optimal solution $x^*$ to this CSP must satisfy $\Psi_e(x_u^*, x_v^*) = 0$ for all edges $e \in E$. Hence, any optimal solution to this CSP also yields an optimal vertex cover solution. Given this reduction from Vertex Cover to a weighted CSP, one can imagine using the techniques of Raghavendra \cite{Rag08} to come up with a similar hardness result for Vertex Cover. However, such an argument fails to work for the following reason: the CSP corresponding to Vertex Cover has a very special relation between the edge constraints and the vertex constraints – the weight of each edge constraint is more than the sum of the weights of the corresponding vertex constraints. The reduction from UGC to such a CSP (which has vertex and edge constraints as defined above) will construct hard instances of such CSPs which may not preserve the required relationship between the weights of vertex and edge constraints. This problem seems to remain whenever we have CSPs where some constraints are strict, i.e., they cannot be violated. This leaves the understanding of problems with strict constraints as the Vertex Cover problem somewhat unsettled.
1.1 Our Work

In this paper, assuming UGC, we present an optimal LP-based algorithm for a class of packing and covering problems. First, we describe the class of covering problems we will study.

Strict Monotone Constraint Satisfaction Problem. A problem $\Pi$ is said to be a $k$-strict and monotone CSP ($k$-sm-CSP) if it consists of a set of vertices $V$ with non-negative weights $\{w_e\}_{e \in E}$ on them, a set of hyperedges of size at most $k$ and for every hyperedge $e \in E$, a constraint $A_e$. These constraints have the following two properties natural for $\{0,1\}$-covering problems.¹

1. The constraints are strict: the constraint corresponding to every hyperedge has to be satisfied.
2. The constraints are monotone: given a feasible solution (a subset of vertices), adding more vertices to the solution keeps it feasible.

The objective is to find a boolean assignment to the vertices so as to satisfy all the hyperedge constraints and minimize the weight of vertices set to 1 (selected). We denote by $\Pi_{A_1, \ldots, A_t}$ a problem in the class $k$-sm-CSP if, for every instance of $\Pi_{A_1, \ldots, A_t}$ and every hyperedge $e$ of this instance, $A_e$ is one of the constraints $\{A_1, \ldots, A_t\}$. It is easy to observe that VERTEX COVER is a special 2-sm-CSP.

An LP for a $k$-sm-CSP problem. One can define the following LP relaxation for any problem in the class $k$-sm-CSP. As written, it may not be immediately clear that it is an LP. We will prove this in Section 2.1 and for the benefit of the reader, we also show in the appendix (Section 6.1) how the standard VERTEX COVER LP can be equivalently written in this form. This relaxation is inspired by the Sherali-Adams [SA90] relaxation and plays a crucial role in our result.

\[
\text{lp}(I) \overset{\text{def}}{=} \minimize \sum_{e \in V} w_e x_e \quad (1)
\]

subject to

\[\forall e=(v_1, v_2, \ldots, v_l) \in E \quad (x_{v_1}, x_{v_2}, \ldots, x_{v_l}) \in \text{ConvexHull}(A_e) \quad (2)\]

\[\forall e \in V \quad 0 \leq x_e \leq 1 \quad (3)\]

Figure 2: LP for $k$-sm-CSP

Here, for a hyperedge $e = \{v_1, \ldots, v_l \}$, $\text{ConvexHull}(A_e)$ denotes the convex hull of all assignments $\sigma \in \{0,1\}^l$ which satisfy the constraint $A_e$. For an instance $I$, let $\text{lp}(I)$ denote the optimum of the LP of Figure 2 for $I$. Also, let $\text{opt}(I)$ denote the value of the optimal integral solution for $I$.

Main Result. The main contribution of this paper is to integrate (a large class of) covering and packing problems in the same conceptual framework as done by Raghavendra for CSPs [Rag08]. We give a rounding algorithm called ROUND (see Figure 3) for the LP of Figure 2. For an instance $I$ of $\Pi$ we first compute $x^*$, the optimal LP-solution for $I$. For a parameter $\varepsilon > 0$, which should be ignored for this discussion, let $\text{round}(I, x^*, \varepsilon)$ denote the value of ROUND. We then show how to start with an instance $I$ of $\Pi$ and give a UNIQUE GAMES-based reduction for $\Pi$ whose soundness and completeness are roughly $\text{lp}(I)$ and $\text{round}(I, x^*, \varepsilon)$ respectively. We also show that ROUND (unconditionally) achieves an approximation ratio equal to the integrality gap, up to an arbitrarily small additive constant, of the LP relaxation. We assume throughout that $k = O(1)$ as our reductions are polynomial-sized when $k$ is a constant.

Theorem 1.1. Let $\Pi$ be a $k$-sm-CSP, $\varepsilon > 0$ for $k = O(1)$, and $I$ be an instance of $\Pi$. Then for every $\delta > 0$, assuming the UGC, it is NP-hard to distinguish instances of $\Pi$ with optimal less than $\text{lp}(I) + \varepsilon + \delta$ from those with optimal more than $\text{round}(I, x^*, \varepsilon) - \delta$. Here $x^*$ is the optimal LP solution for $I$.

As a corollary we can deduce the following: we set $\delta \overset{\text{def}}{=} \varepsilon$ and note that for any instance $I$, $\text{round}(I, x^*, \varepsilon)$ is at most $\text{opt}(I)$.

Corollary 1.2. Let $\Pi$ be in the class $k$-sm-CSP and $I$ be an instance of $\Pi$. Then for every $\delta > 0$, assuming the UGC, it is NP-hard to distinguish instances of $\Pi$ with optimal less than $\text{lp}(I) + 2\delta$ from those with optimal more than $\text{opt}(I) - \delta$.

The class $k$-sm-CSP falls under the class of covering problems. One can also define a similar class of problems for packing problems, namely Packing-$k$-sm-CSP. The only differences would be (1) we would be interested in maximizing the total weight of vertices set to 1, and (2) the constraints would be downward monotone, i.e., removing some vertices from the solution would still keep it feasible. All our results translate to the setting of packing problems in the natural manner. A more detailed description of Packing-$k$-sm-CSP and the rounding algorithm for this class appears in the Appendix (Section 6.6).

¹Our results readily generalize for problems over larger but constant-sized alphabets. We restrict ourselves to the alphabet $\{0,1\}$ in this paper.
1.2 Overview and Techniques

In this section we outline the proof of Theorem 1.1. We explain the main ideas with the canonical example of Vertex Cover. Unlike previous work, we will be interested in instances where ROUND fails i.e., where the value round(I, x∗, ε) is much larger than lp(I). Note that this is a weaker condition than the instance being an integrality gap instance (as considered previously for CSPs), where the value opt(I) is much larger than lp(I).

In particular, for Vertex Cover, ROUND performs poorly on a graph with a single edge, which is not an integrality gap instance because the integer optimum and the LP optimum are both equal to 1. One optimal LP solution is to set a value of 1/2 for both the end points, and thus, satisfying the constraint corresponding to this edge. ROUND would then end up choosing both the end points in the cover, thus, being off by a factor 2 in the objective. We show a reduction from Unique Games that uses this instance to obtain a factor 2 − ε hardness for Vertex Cover. The reduction produces the Khot-Regev graph although our analysis is conceptually simpler and uses the, by now standard, invariance principle. Note that the inapproximability obtained is at least as good as the integrality gap of the LP because the optimal solution is at least as good as the one output by ROUND.

Given an instance of Vertex Cover along with an LP solution, we prove that the best rounding scheme, assuming the UGC, is one which sets the variables to 1 or 0 by solely looking at the value of the variables. We do so by picking a Unique Games instance and replacing each vertex of the unique game with several blocks of vertices, one for every distinct value the LP solution takes (one can think of having one block for every variable in the LP, but we will later need to identify variables taking the same value). We then introduce constraints across the blocks inspired by the LP solution such that if the Unique Games instance has a good labeling, then there is a way to choose a fraction of each of the blocks such that all the edges are covered. Further, the fraction selected in each block has measure exactly equal to the total value of the corresponding variables in the LP solution.

Next, we show that if the Unique Games instance has no good solution, then any solution can be converted to a solution that either completely chooses a block or ignores it completely while losing only a small additive error in the objective. We use the invariance principle and gaussian stability estimates to prove that if a particular block is partially selected, then, there are a bunch of constraints that are completely contained in the unselected part. Thus, given that the solution satisfies every constraint (covers all edges), the partially selected blocks might as well have been completely unselected without violating any constraint. If we think of selecting a block as setting the corresponding variable to 1 and not selecting as setting it to 0, this naturally corresponds to a rounding of the LP solution solely based on the value of each variable: exactly the space of solutions ROUND searches over.

As it is, this does not say much since the LP value could assign completely distinct values to all the variables. However, we can always convert such an LP solution to one that takes only a constant (1/ε) number of distinct values while losing a small additive error (ε) in the objective. This naturally gives a rounding scheme, which as the first step discretizes the LP solution to have a small number of distinct values before trying out every possible rounding of the values. The rounding scheme remains exactly the same for the general version: solve the linear program, fix the solution to one with a small number of distinct values and then exhaustively search over all possible roundings of the values.

1.3 Further Discussion and Related Work

LP inspired hardness results. There are several problems for which the best known inapproximability results have been obtained as follows: first construct integrality gap instances for the standard LP relaxations for these problems and then use these instances as guides for constructing hardness reductions based on standard complexity theoretic assumptions. These reductions yield inapproximability ratios quite close to the actual integrality gaps. Examples include Asymmetric k-center[CGH+04], Group Steiner Tree[HK03] and Average Flow-time on Parallel Machines[GK07]. Assuming UGC, our result proves hardness of a large class of problems in a similar spirit. However, instead of explicitly constructing integrality gap examples for such problems, we give a more direct and intuitive proof that the integrality gap is close to the actual hardness of such problems. We note that the only other result for LPs similar in flavor as ours, though unrelated, is that of [MNRS08] for Multi-Way Cut.

Unique Games Conjecture. Since its inception, the UGC of Khot [Kho02] has been used to obtain a host of inapproximability results [Kho02, KV05, CKK+06, KKKM07, KR08, MNRS08, GMR08, Rag08, CGM09] and, it implies optimal hardness of approximation results for problems such as Maximum Cut [KKMO07] and Vertex Cover [KR08, BK09].

Very recently, for the problem of Vertex Cover, a similar analysis using the invariance principle was also proved by Austrin, Khot and Safra [AKS09]. They were motivated by the problem of proving hardness of approximating Vertex Cover on bounded degree graphs where as the goal of this paper is to establish the optimality of LP-based algorithms for problems similar to Vertex Cover.
1.4 Rest of the paper.

In Section 2, we give a detailed outline of the proof of Theorem 1.1. In Section 2.1 we formally define the class of problems we shall be interested in. In Section 2.2, we outline the properties of the dictatorship test which leads to the proof of Theorem 1.1. We describe the rounding algorithm and prove its optimality in Section 3. We give all the details of the construction and the properties of the dictatorship test in Section 4. This requires us to prove some properties of a feasible solution to the LP, which we describe in Section 4.1. The actual reduction from UGC to a problem in the class k-sm-CSP builds on the construction of the dictatorship function in a standard manner – we describe this in the appendix (Section 6.5). Finally, we describe our framework for packing problems in Section 6.6 in the appendix.

2 Proof of Theorem 1.1

In this section we will reduce the task of proving Theorem 1.1 to constructing a dictatorship test. Once we have stated the claim for the dictatorship test, it would be standard to convert it into a UGC-based hardness result and deduce Theorem 1.1. The soundness of this dictatorship test, in turn, relies on the rounding algorithm ROUND of Figure 3 which is described in Section 3. We start with some necessary preliminaries to describe the problems and the LP we will consider for them.

2.1 Preliminaries

Given distinct \( x, y \in [0, 1]^k \), we say \( y \succeq x \), if for every \( i \in [k] \), \( y_i \geq x_i \). Further, a subset \( A \subseteq \{0, 1\}^k \) is said to be upward monotone if for every \( x \in A \), and every \( y \) such that \( y \succeq x \), it follows that \( y \in A \).

**Definition 2.1** (The class k-sm-CSP). Let \( k \) be a positive integer. An instance of type k-sm-CSP is given by

\[
I = (V, E, |A_e|_{e \in E}, \{w_e\}_{e \in V})
\]

where:

- \( V = \{v_1, v_2, \ldots, v_n\} \) denotes a set of variables/vertices taking values over \([0, 1]\) along with non-negative weights such that \( \sum_{e \in V} w_e = 1 \).
- \( E \) denotes a collection of hyperedges, each on at most \( k \) vertices. For each hyperedge \( e \in E \), there is a constraint \( A_e \) which is an upward monotone set denoting the set of accepted configurations of the vertices in \( e \).

The objective is to find an assignment \( \Lambda : V \to \{0, 1\} \) for the vertices in \( V \) that minimizes \( \sum_{e \in V} w_e \Lambda(v) \) such that for each \( e = (v_1, v_2, \ldots, v_k) \), \( \Lambda(v_1), \ldots, \Lambda(v_k) \) \( \in A_e \). A k-sm-CSP \( \Pi \) is given by upward monotone sets \( \{A_1, \ldots, A_t\} \). Every instance of \( \Pi \) is supposed to have its constraints for the hyperedges to be one of \( \{A_1, \ldots, A_t\} \). For simplicity, we will assume that the size of each hyperedge is exactly \( k \). Our proofs also hold when hyperedges have size at most \( k \).

**Definition 2.2.** For a set \( A \subseteq \{0, 1\}^k \), define \( \text{ConvexHull}(A) \) as the convex hull of elements in \( A \). Note that any element \( x \in \text{ConvexHull}(A) \) can be expressed as \( \sum_{\sigma \in A} \lambda_\sigma \cdot \sigma \), where \( \lambda_\sigma \) can be thought of as giving a probability distribution over elements of \( A \).

The LP relaxation for k-sm-CSP appears in Figure 2. On an instance \( I \) and a feasible solution \( x \) to LP(I), we will let \( \text{val}(I, x) \) to denote the objective of LP(I). We now show that this indeed is an LP by explicitly writing the constraints (2) as linear constraints. Consider an edge \( e = (u_1, \ldots, u_k) \in E \). We define variables \( x^e_\sigma \), where \( \sigma \in \{0, 1\}^k \) and it varies over all elements of \( A_e \). The constraint (2) can now be written as

\[
(x_{u_1}, x_{u_2}, \ldots, x_{u_k}) = \sum_{\sigma \in A_e} \lambda^e_\sigma \cdot \sigma
\]

\[
\forall \sigma \in A_e, \lambda^e_\sigma \geq 0
\]

\[
\sum_{\sigma \in A_e} \lambda^e_\sigma = 1.
\]

In the appendix (Section 6.1), we show that for the VERTEX COVER and HYPERGRAPH VERTEX COVER problems, this LP is at least as strong as the standard LP relaxations for these problems.
2.2 Dictatorship Function

We now describe the properties of the dictatorship test. In fact, we prefer to refer to it as a dictatorship function as it takes some inputs and has an output rather than an acceptance predicate.

Our dictatorship function $D_{I,x,m}^\Pi(r,\delta)$ takes as input an instance $I$ of a problem $\Pi$, a solution $x$ to the LP relaxation (Figure 2) for this instance, and parameters $m, r$ and $\delta$. $r$ would be the label set size of the UNIQUE GAMES instance we combine this dictatorship function with to get the actual reduction for Theorem 1.1 and can be ignored for now. $m$ is an upper bound on the number of distinct values the entries in the vector $x$ are allowed to take. We will often refer to $\delta$ as $\frac{1}{m-1}$. $\delta$ is a smoothening parameter, essential for the application of the invariance principle, and can be ignored for now. The dictatorship function outputs another instance $D$ of $\Pi$. The vertex set $V(D)$ of this instance would be $[m] \times \{0, 1\}'$ and we defer the precise description of the output instance for Section 4.2. Recall that $\text{round}(I, x, \epsilon)$ denotes the value of the rounding algorithm $\text{ROUND}(I, x, \epsilon)$. Even though we will describe the algorithm in the next section, for now, it is sufficient to know that the algorithm produces an integral solution for $I$ from a feasible solution $x$ to $\text{LP}(I)$ after it has perturbed $x$ and made sure that its variables take at most $m$ distinct values. In particular, $\text{round}(I, x, \epsilon) \leq \text{opt}(I)$. Now, we can state the main claim regarding our dictatorship function.

**Lemma 2.3.** (Informal Version) The dictatorship function $D_{I,x,m}^\Pi(r,\delta)$ has the following properties:

1. **Completeness:** There are $r$ “dictator” assignments to $V(D)$ each of which satisfy all the constraints of $D$ and each costs at most $\text{val}(I, x) + \delta$.

2. **Soundness:** Every assignment which is “far from being a dictator” assignment and satisfies all the constraints in $D$ must have cost at least $\text{round}(I, x, \epsilon) - \delta$.

We leave the precise definition of “dictator” and “far from being a dictator” for Section 4.2. The proof of this lemma also appears in Section 4.2. For a fixed instance $I$, to maximize the gap between $\text{val}(I, x)$ and $\text{round}(I, x, \epsilon)$ one should use $x = x^*$, the optimal solution to $\text{LP}(I)$. The problem is that, then, we are not guaranteed that the variables in $x^*$ take at most $m$ distinct values. But this is easy: since the variables take value between 0 and 1, one can just bucket them into bins of width $\epsilon$ and lose only an additional $\epsilon$ in the completeness in the lemma above. Hence, we can obtain the following corollary.

**Corollary 2.4.** The dictatorship function $D_{I,x,m}^\Pi(r,\delta)$ has the following properties:

1. **Completeness:** There are $r$ dictator assignments to $V(D)$ each of which satisfy all the constraints of $D$ and each costs at most $\text{lp}(I) + \epsilon + \delta$.

2. **Soundness:** Every assignment which is “far from being a dictator” assignment and satisfies all the constraints in $D$ must have cost at least $\text{round}(I, x^*, \epsilon) - \delta$.

Here $x^*$ is the optimal LP solution for $I$.

The corollary above can be converted to a UNIQUE GAMES-based hardness result for $\Pi$. The following is just a reformulation of Theorem 1.1 and will be proved formally in Section 6.5.

**Theorem 2.5.** Let $\Pi$ be a $k$-sm-CSP, $\epsilon > 0$ for $k = O(1)$, and $I$ be an instance of $\Pi$. Then for every $\delta > 0$, given an input instance $J$ of $\Pi$, assuming the UGC, it is NP-hard to distinguish between the following:

1. Completeness: $\text{opt}(J) \leq \text{lp}(I) + \epsilon + \delta$.

2. Soundness: $\text{opt}(J) \geq \text{round}(I, x^*, \epsilon) - \delta$.

Here $x^*$ is the optimal LP solution for $I$.

3 The Rounding Algorithm and its Optimality

In this section we describe our rounding algorithm $\text{ROUND}$ and prove that it achieves the integrality gap unconditionally. Theorem 1.1 implies that it is not possible to beat this integrality gap assuming the UGC. Hence, this algorithm is optimal.
The algorithm. The algorithm will use a parameter $\epsilon$. We assume without loss of generality that $1/\epsilon$ is an integer. We first define a way of perturbing a solution $x$ to LP($I$) (Figure 2) such that the number of distinct values the variables of $x$ take is at most $1/\epsilon + 1$.

**Definition 3.1.** Given an $x$ such that $0 \leq x_u \leq 1$ for all $u \in V$, and a parameter $\epsilon > 0$, define $x^\epsilon$ as follows – for each $u \in V$, let $k_u$ be the integer satisfying $k_u \epsilon < x_u \leq (k_u + 1) \epsilon$, then $x_u^\epsilon \overset{\text{def}}{=} (k_u + 1) \epsilon$ (if $x_u = 0$, we define $x_u^\epsilon$ to be 0 as well).

In other words, $x^\epsilon$ is obtained from $x$ by rounding up each coordinate to the nearest integral multiple of $\epsilon$ (note that this value will not exceed 1 because $1/\epsilon$ is an integer). First we observe the following simple fact.

**Fact 3.2.** Let $x$ be a feasible solution to LP($I$). Then

1. $x^\epsilon$ is feasible for LP($I$).
2. $\text{val}(I, x^\epsilon) \leq \text{val}(I, x) + \epsilon$.

The proof this fact appears in the appendix (Section 6.2).

The algorithm ROUND is described in Figure 3. This algorithm takes as input an instance $I$, a feasible solution $x$ to LP($I$) and a parameter $\epsilon > 0$. We denote round($I, x, \epsilon$) as the value of the integral solution returned by ROUND($I, x, \epsilon$). First, the algorithm perturbs $x$ to $x^\epsilon$ to make sure that the number of distinct values taken by the variables in $x^\epsilon$ is at most $m = O(1/\epsilon)$, which is to be thought of as a (large) constant. Thus, the variables fall into $m$ buckets and now, the rounding algorithm goes over all possible assignments to these constantly many buckets and outputs the assignment with the least cost.

The optimality of the rounding algorithm. We quickly observe that ROUND achieves the integrality gap.

**Lemma 3.3.** Let $\gamma^*(\Pi)$ be the worst-case approximation ratio (integrality gap) achieved by the LP relaxation for the problem $\Pi$, i.e., $\gamma^*(\Pi) \overset{\text{def}}{=} \sup_I(\text{opt}(I)/\text{lp}(I))$, where the supremum is taken over all instances $I$ of $\Pi$. Then, for any given instance $\mathcal{J}$, optimal LP solution $x$ and $\epsilon > 0$, $\text{round}(\mathcal{J}, x, \epsilon) \leq \gamma^*(\Pi) \cdot (\text{opt}(\mathcal{J}) + \epsilon)$.

**Proof.** Consider an input $(\mathcal{J}, x, \epsilon)$ to the algorithm ROUND. We define a new instance $\mathcal{J}'$ of $\Pi$ as follows: the set of variables $V' = \{0, \ldots, 1/\epsilon + 1\}$ and hyperedge set $E' = \{(i_1, \ldots, i_k) \mid (v_1, \ldots, v_k) \in E \text{ and } x_u^\epsilon = i_j \cdot \epsilon \text{ for all } j \in \{k\}\}$. We take the weight $w_i$ of $i \in V'$ to be $\sum_{e : i \in e} w_e$ and take constraint $A_{e'}$ for an edge $e' \in E'$ to be the same as $A_e$ for the corresponding edge in $e \in E$. Then, since ROUND($\mathcal{J}, x, \epsilon$) searches over all feasible assignments to variables in $\mathcal{J}'$, we get that $\text{round}(\mathcal{J}, x, \epsilon) = \text{opt}(\mathcal{J}')$. Hence, we get

$$\text{round}(\mathcal{J}, x, \epsilon) = \text{opt}(\mathcal{J}') \leq \gamma^*(\Pi) \cdot \text{lp}(\mathcal{J}') \overset{\text{Fact 3.2}}{\leq} \gamma^*(\Pi) \cdot (\text{lp}(\mathcal{J}) + \epsilon) \leq \gamma^*(\Pi) \cdot (\text{opt}(\mathcal{J}) + \epsilon).$$

\[\square\]

**INPUT:** An instance $I = (V, E, \{A_e\}_{e \in E}, \{w_e\}_{e \in V})$ of a problem in $k$-sm-CSP, a feasible solution $x$ to LP($I$) and a parameter $\epsilon > 0$. Let $m := 1/\epsilon$.

**OUTPUT:** A labeling $\Lambda : V \rightarrow \{0, 1\}$.

1. Construct the solution $x^\epsilon$.
2. For every $z \in \{0, 1\}^m$, construct a 0-1 solution $\Lambda^z$ as follows: $\Lambda^z_e \overset{\text{def}}{=} z_j$ if $x^\epsilon_u = j \epsilon$.
3. Output the solution $\Lambda^z$ which has the smallest objective value among all feasible solutions in $\{\Lambda^z_z \mid z \in \{0, 1\}^m\}$.

Figure 3: Algorithm ROUND
Deducing the Khot-Regev result. As an application of Theorem 1.1, we prove the result of Khot and Regev [KR08] which states that assuming UGC, it is NP-hard to get \((k-\epsilon)\)-approximation algorithm for the \(k\)-HYPERGRAPH VERTEX COVER problem for any constant \(\epsilon > 0\). Consider the following instance \(I\) of \(k\)-HYPERGRAPH VERTEX COVER – we are given a set \(V\) of size \(k\), and there is only one hyperedge in \(E\), namely, the set of all vertices in \(V\). The weight of every vertex is \(1/k\). Consider the solution \(x\) which assigns value \(1/k\) to all variables \(x_v\). It is easy to check that it is feasible to our LP relaxation. The value of the solution \(x\) is \(1/k\). Let us now see how the algorithm \(\text{ROUND}(I, x, \epsilon)\), where \(\epsilon < 1/k\), rounds the solution \(x\). All entries in \(x^\epsilon\) will still be same. Hence, the rounding algorithm will consider only two options – either pick all vertices in \(V\), or do not pick any vertex. Since the latter case yields an infeasible solution, it will output the set \(V\), which has value 1. Theorem 1.1 now implies that assuming UGC, it is NP-hard to distinguish between instances of \(k\)-HYPERGRAPH VERTEX COVER where the optimal value is at most \(1/k - 2\epsilon\) from those where the optimal value is more than \(1 - \epsilon\). Note that the integrality gap of \(LP(I)\) is 1. Still we are able to argue hardness of \(k\)-HYPERGRAPH VERTEX COVER problem starting from such an instance because the algorithm \(\text{ROUND}\) performs poorly on this instance. In this sense, the statement of Theorem 1.1 is stronger than that of Corollary 1.2.

4 Dictatorship Function

In this section we give details of the dictatorship function. The dictatorship function takes as input an instance \(I\) of the problem, a feasible solution \(x\) to \(LP(I)\) and parameters \(m, \delta\) and \(r\). The entries in the solution \(x\) take at most \(m\) distinct values. The parameter \(r\) is related to the label size in the UNIQUE GAMES instance that is used for the reduction, and can be assumed to be an arbitrary quantity for this discussion. The output of the dictatorship function is another instance \(D\) of the same problem. The vertex set of this instance is \([m] \times \{0, 1\}^r\), which we can think of as \(m\) blocks. The hyperedges in \(D\) are constructed roughly as follows – for every hyperedge \(e\) in the input instance \(I\), we pick \(r\) hyperedges from the set \(A_e\) by a randomized process. We use these \(r\) hyperedges to construct one hyperedge in \(D\) which spans across \(k\) suitably chosen blocks in \(D\). The set of hyperedges in \(D\) consist of hyperedges which can be obtained in this manner with strictly positive probability. Note that even though these probabilities are not explicitly required for the description of \(D\), they are still useful for the soundness analysis of the dictatorship function.

Given a hyperedge \(e\) in the instance \(I\), the probabilities with which we select \(r\) edges from \(A_e\) are obtained by using the fact that \(x\) is a feasible solution to \(LP(I)\). This allows us to express \(x\) as a convex combination of elements in \(A_e\) and the coefficients in this convex combination give us the requisite probabilities. The analysis of the dictatorship function uses the invariance principle, which requires that the minimum non-zero probability of an element in \(A_e\) is not too small, and a suitably defined “correlation graph” is connected. We achieve these two properties by using the parameter \(\delta\) to “smoothen” the probabilities obtained from the solution \(x\). We now define these probability distributions and their smoothenings more formally below.

4.1 Probability Distribution from the LP solution

We define the notion of smoothening the distribution obtained by restricted \(x\) to a hyperedge \(e\).

**Definition 4.1.** Let \(x\) be a feasible solution to \(LP(I)\). For a hyperedge \(e\), let \(x_e\) be the vector obtained by restricting \(x\) to only those vertices which belong to \(e\). \(P^i_e\) shall denote the probability distribution over the vectors in \([0, 1]^k\) corresponding to elements of \(A_e\) that arises from the fact that \(x_e \in \text{ConvexHull}(A_e)\). For a parameter \(\delta > 0\), define a random function \(f^\delta : [0, 1]^k \rightarrow [0, 1]^k\) which satisfies the following property independently for each \(i\):

\[
f^\delta(x)_i \equiv \begin{cases} x_i & \text{with probability } 1 - \delta \\ 1 & \text{with probability } \delta \end{cases}
\]

Now define a distribution \(M_\delta(P^\epsilon_e)\) over \([0, 1]^k\) where

\[
M_\delta(P^\epsilon_e)(z) \equiv \mathbb{E}_{z' \sim f} [f(z') = z],
\]

where \(z'\) is drawn according to distribution \(P^\epsilon_e\) and \(f\) from the space of function from \([0, 1]^k\) to \([0, 1]^k\) as described above.

**Remark 4.2.** Note that for a hyperedge \(e\), the support of \(P^\epsilon_e\) is a subset of \(A_e\). Since \(A_e\) is upward monotone, the same fact holds for \(M_\delta(P^\epsilon_e)\) as well.

**Definition 4.3.** Let \(P\) be a distribution on \([0, 1]^k\). Define \(\text{margin}_i(P), 1 \leq i \leq k\) as the following distribution on \([0, 1]\):

\[
\text{margin}_i(P)(b) \equiv \sum_{b_1, \ldots, b_{i-1}, b_{i+1}, \ldots, b_k} P(b_1, \ldots, b_{i-1}, b, b_{i+1}, \ldots, b_k).
\]
The following fact, whose proof is easy to check, shows that the marginals of the distributions $P^z_e$ and $M_δ(P^z_e)$ on a single coordinate can be easily expressed in terms of $x$.

**Fact 4.4.** Let $e = (u_1, \ldots, u_k)$ be a hyperedge in an instance $I$. Then, $E_{\text{margin}(P^z_e)}(b) = x_{u_1}$, and $E_{\text{margin}(M_δ(P^z_e))}(b) = (1-δ)x_{u_1} + δ$.

**Fact 4.5.** For a hyperedge $e$, let $α$ denote $\min_u[P^z_e(\omega) : P^z_e(\omega) > 0]$. Then $\min_u[M_δ(P^z_e(\omega)) : M_δ(P^z_e(\omega)) > 0]$ is at least $δ^k \cdot α$.

A feasible solution $x$ satisfies the property that $(x_{u_1}, \ldots, x_{u_k})$ can be expressed a convex combination of vectors in $A_e$ for every $e = (u_1, \ldots, u_k) \in E$. The following lemma shows that under some conditions on $x$, the non-zero coefficients of this convex combination are large enough. This shall be useful in our application of the invariance principle. We defer the proof to appendix (Section 6.3).

**Lemma 4.6.** Let $A$ be a upward monotone subset of $\{0, 1\}^k$ and let $(x_1, x_2, \ldots, x_k) \in \text{ConvexHull}(A)$ such that each $x_u$ is an integral multiple of $e$ (assume that $\frac{1}{e}$ is an integer). Then, there is a distribution $P$ over $A$ such that the minimum probability of any atom in $P$ is at least $\frac{δx}{27}$.

### 4.2 Description and Properties of the Dictatorship Function

In this section, we first describe the parameters of the dictatorship function and the output instance that it produces. Then we give a more formal statement of Lemma 2.3 in Lemma 4.9 and Theorem 4.10. We then prove these and hence, complete the proof of Lemma 2.3 and Corollary 2.4.

**Parameters of** $\text{Dict}^H_{I, x, m}(r, δ)$.

1. **Starting Instance.** An instance $I = (V = \{u_1, \ldots, u_n\}, E, \{A_e\}_{e \in E}, \{w_u\}_{u \in V})$ of $Π$.

2. **Solution to LP($I$).** A vector $x = (x_{u_1}, \ldots, x_{u_n})$ which is a feasible solution to LP($I$).

3. **Multiplicity Parameter.** $m$ denotes the number of distinct values in the vector $x$ and let $p_1, \ldots, p_m$ denote these distinct values. Let $B : V \mapsto \{1, 2, \ldots, m\}$ such that $B(u_1) := b$ whenever $x_{u_1} = p_b$ for some $b \in \{1, \ldots, m\}$.

4. **Smoothening Parameter.** $δ > 0$. For a feasible solution $x$ to LP($I$) and for every edge $e \in E$, we use this parameter to define the distribution $M_δ(P^z_e)$. The solution $x$ shall satisfy the conditions of Lemma 4.6, and, hence, Fact 4.5 implies that the minimum probability of an atom in $M_δ(P^z_e)$ is at least $\frac{δx}{27}$.

5. **Repetition Parameter.** A positive integer $r$. ($r$ would be the size of the label set of the Unique Games instance to be used in the hardness reduction.)

**The Output Instance.** $\text{Dict}^H_{I, x, m}(r, δ)$ outputs the following instance $D$ of $Π$

1. **Vertex Set.** The vertex set of $D$ is $V(D) := \{m\} \times \{0, 1\}^r$.

2. **Weights on Vertices.** Let $q_b \overset{\text{def}}{=} p_b(1 - δ) + δ$ for $b \in \{1, 2, \ldots, m\}$. The weight of a vertex $(b, y) \in D$, $w_D((b, y)) \overset{\text{def}}{=} μ_{q_b}(y) \sum_{u \in V | x_u = p_b} w_u$.

Note that since $\sum_{u \in V} w_u = 1$, $\sum_{v \in V(D)} w_D(v) = 1$.

3. **Hyper-edges and Constraints.** The set of constraints in $D$ is the union of every constraint output with positive probability by the following procedure:

   (a) Pick a random hyperedge $e = (u_1, u_2, \ldots, u_k)$ from $I$ and let $A_e$ denote the constraint corresponding to it.

   (b) Sample $r$ independent copies $(z_{u_1}^1, z_{u_1}^2, \ldots, z_{u_1}^r)$ from the distribution $M_δ(P^z_e)$.

   (c) Let the corresponding hyperedge in $D$ be $\left( (B(u_1), (z_{u_1}^1, z_{u_1}^2, \ldots, z_{u_1}^r)), (B(u_2), (z_{u_2}^1, z_{u_2}^2, \ldots, z_{u_2}^r)), \ldots, (B(u_k), (z_{u_k}^1, z_{u_k}^2, \ldots, z_{u_k}^r)) \right)$

   and the constraint corresponding to it be $A_e$. 

8
We now define the notions “dictator” and “far from being dictator”, and then give formal statements of Lemma 2.3.

**Definition 4.7.** A set \( S \subseteq [m] \times \{0, 1\}' \) is said to be a dictator if there exists an \( i \in [r] \) such that \( S = \{(b, z) : z_i = 1\} \).

For a \( S \subseteq [m] \times \{0, 1\}' \), define \( S_b \overset{\text{def}}{=} S \cap (b, [0, 1]' \). Further, define functions \( f_b^S : \{0, 1\}' \rightarrow \{0, 1\} \) to be the indicator function of the complement of \( S_b \). We refer to a subset of vertices of \( D \) of the form \((b, [0, 1]'\) as the hypercube corresponding to \( b \). For \( 0 \leq q \leq 1 \), let \( z \sim \mu_q \) denote a string drawn from the \( q \)-biased distribution on \( \{0, 1\}' \). Given \( i \in [r], b \in [m], \) the degree \( d \)-influence of the \( i \)-th coordinate of \( f_b^S \), \( \Inf_i^d(f_b^S) \) with respect to the measure \( \mu_q \) is defined in Section 6.4.1.

**Definition 4.8.** Given \( \tau, d \geq 0 \), a set \( S \subseteq [m] \times \{0, 1\}' \) is said to be \((\tau, d)\)-pseudo-random if for every \( b \in [m] \) and every \( i \in [r] \), \( \Inf_i^d(f_b^S) \leq \tau \).

Now we state the completeness and soundness properties of the dictatorship function.

**Lemma 4.9.** (Completeness.) Suppose \( S \subseteq [m] \times \{0, 1\}' \) is a dictator. Then \( S \) satisfies all the constraints of \( \mathcal{D} \) and \( w_D(S) \leq \val(I, x) + \delta \).

Observe that if we take the optimal solution \( x^* \) of \( \lp(I) \) and use the corresponding perturbed solution \( x^\varepsilon \) as input to the dictatorship function, then Lemma 4.9 combined with Fact 3.2 implies the first statement in Corollary 2.4.

**Theorem 4.10.** (Soundness.) For every \( \delta > 0 \), there exists a \( d, \tau \) such that if \( S \subseteq [m] \times \{0, 1\}' \) satisfies all the constraints of \( \mathcal{D} \) and is \((\tau, d)\)-pseudo-random, then \( w_D(S) \geq \round(I, x, \varepsilon) - \delta \).

The construction of the dictatorship function can be extended to give a reduction from **Unique Games** to a problem in the class \( k\text{-sm-CSP} \). The completeness and soundness of the dictatorship function translate to that for the reduction, which allows us to prove Theorem 2.5. We describe this reduction in the appendix (Section 6.5).

**Proofs of Completeness and Soundness Properties** Now we give proofs of Lemma 4.9 and Theorem 4.10.

**Proof of Lemma 4.9.** Let \( i \) be such that \( S = \{(b, z) : z_i = 1\} \). For any hyperedge \( e \in E \), recall that the support of \( M_\delta(P^*_e) \) is a subset of \( A_e \). Hence, any \((z_{a_1}, z_{a_2}, \ldots, z_{a_\ell}) \leftarrow M_\delta(P^*_e) \) always satisfies the constraint \( A_e \). Thus, the set \( S \) satisfies every constraint of the instance \( \mathcal{D} \). The total weight of the set \( S \) is

\[
\sum_{b \in [m]} \sum_{z_i = 1} \mu_b(z) \sum_{u \in [n]} w_u = \sum_{b \in [m]} \sum_{u \in [n]} q_b \sum_{u \in [n]} w_u = \sum_{u} w_u x_u(1 - \delta) + \delta \leq \val(I, x) + \delta.
\]

\[\square\]

We now prove the soundness of the dictatorship test. The crux of the proof is to show that given a subset \( S \subseteq [m] \times \{0, 1\}' \) satisfying all the constraints in \( \mathcal{D} \), one can find a subset \( J \subseteq [m] \) such that \( T_J \overset{\text{def}}{=} \cup_{b \in J} (b, [0, 1]' \) satisfies all the constraints in \( \mathcal{D} \) and \( w_D(T_J) \leq w_D(S) + \delta \).

**Proof of Theorem 4.10.** Define

\[
J \overset{\text{def}}{=} \left\{ b \mid \mathbb{E}_{z \sim \mu_q} f_b^S(z) \leq \delta \right\}.
\]

Fix a particular hyperedge \( e = (u_1, u_2, \ldots, u_k) \in E \) of the instance \( I \). Let

\[
R_e \overset{\text{def}}{=} \{ u_i \in e \mid B(u_i) \notin J \}.
\]

We will deduce the following fact from the Invariance Principle of Mossel [Mos08]. We give a detailed description of the invariance principle in the appendix (Section 6.4.1). The proof of the following fact is also deferred to the appendix (Section 6.4).

**Fact 4.11.**

\[
\mathbb{E}_{\Pi_{u \in R_e} f_b^S(z(u))} > 0.
\]
In the expectation above, the argument \( z^{(u)} \) of \( f_{B(u)}^S \) is chosen with the \( q_{B(u)} \)-biased measure on \( \{0, 1\}^r \) independently for each \( u \in R_e \). Since \( f_{B(u)}^S \in \{0, 1\} \) and, in particular non-negative, for each \( b \in [m] \), this fact implies that there is a hyperedge in \( D \) that queries the hypercubes corresponding to \((u_1, u_2, \ldots, u_k)\) at \( z^{(u_1)}, \ldots, z^{(u_k)} \) respectively such that for every \( u \in R_e \), \( f_{B(u)}^S(z^{(u)}) = 1 \).
Since \( f_{S_b} \) is the indicator of the complement of \( S_b \), this means that the constraint was satisfied solely by the hypercubes in \( J \). Thus, all the constraints of \( D \) would also be satisfied by the set \( T_J \). Note that since \( T_J \) selects hypercubes that are already \( 1 - \delta \) fraction covered by \( S \), \( w_D(T_J) \leq w_D(S) + \delta \).

Further, since \( T_J \) either completely chooses a particular hypercube or completely ignores it, this corresponds to one of the assignments that the rounding algorithm iterates through on the input \((I, x, \epsilon)\). This implies that \( \text{round}(I, x, \epsilon) \) is at most \( w_D(T_J) \). This completes the proof of the theorem. □

6 Appendix

6.1 Comparison of our LP with standard LP’s for Vertex Cover and Hypergraph Vertex Cover

We compare the LP relaxation of Figure 2 to the standard LP’s for the Vertex Cover and k-Hypergraph Vertex Cover problems. For the Vertex Cover problem, the two LP’s are equivalent. Fix an instance $I$ of the Vertex Cover problem. For an edge $e = uv$, the set $A_e = \{(0, 1), (1, 0), (1, 1)\}$. Hence, an element of ConvexHu11($A_e$) can be written as $A_1(0, 1) + A_2(1, 0) + A_3(1, 1) = (A_1 + A_2, A_1 + A_3)$, where $A_i = 0$ for $i = 1, 2, 3$ and $\sum_{i=1}^{3} A_i = 1$. Now, $x_u = A_2 + A_3, x_v = A_1 + A_3$ implies that $x_u + x_v \geq 1$. Conversely, it is easy to check that given values $x_u, x_v \geq 0$ such that $x_u + x_v \geq 1$, one can find corresponding $A_i$ values. Thus, the standard LP and our LP for Vertex Cover problem are equivalent.

We now show that the LP of Figure 2 is stronger than the usual LP relaxation for k-Hypergraph Vertex Cover. An instance of $k$-Hypergraph Vertex Cover is specified by a ground set $V$ and a set $E \subseteq V^k$. Each vertex $u \in V$ has weight $w_u$ and the goal is to find a minimum weight subset of $V$ which contains at least one element from each hyperedge in $E$. The usual LP for k-Hypergraph Vertex Cover is written as follows:

\[
\begin{align*}
\text{minimize} & \quad \sum_{e \in V} w_e x_e \\
\text{subject to} & \quad \forall e = u_1, u_2, \ldots u_k \in E \quad x_{u_1} + \cdots + x_{u_k} \geq 1 \\
& \quad \forall e \in V \quad x_e \geq 0
\end{align*}
\]

The set $A_e$ for this problem contains all the elements of $\{0, 1\}^k$ except the all zero vector $(0, \ldots, 0)$. An element $(x_{u_1}, \ldots, x_{u_k}) \in A_e$ has the property that $x_{u_1} + \cdots + x_{u_k} \geq 1$ and so the same holds for any element in ConvexHu11($A_e$). Hence, constraints (2) imply constraints (5).

6.2 Details of Section 3

We prove Fact 3.2 which we state below.

**Fact 6.1.** Let $x$ be a feasible solution to LP($I$). Then

1. $x^\ell$ is feasible for LP($I$).
2. $\text{val}(I, x^\ell) \leq \text{val}(I, x) + \epsilon$.

**Proof.** We first prove the first statement. It is enough to prove this for $x'$ where $x'$ differs from $x$ on only one coordinate $u$. Fix an edge $e = (u_1, \ldots, u_k)$ and without loss of generality assume that $u = u_1$. Let $A_{e, \sigma} \in A_e$ be the coefficients in the convex combination of vectors in $A_e$ which yield $(x_{u_1}, \ldots, x_{u_k})$. Let $A'_{e, \sigma}$ be the set of $\sigma$ for which $\sigma_1 = 0$.

For each $\sigma \in A'_{e, \sigma}$, define $m(\sigma)$ as vector which is same as $\sigma$ except that $\sigma_1' = 1$. Clearly, $m(\sigma) \in A_e$ as well. Now consider the vector $\sum_{\sigma \in A_{e, \sigma}} A_{e, \sigma} + \sum_{\sigma' \in A'_{e, \sigma}} A_{e, \sigma}' m(\sigma)$. This is equal to $(1, x_{u_2}, \ldots, x_{u_k})$. Thus, we have shown that the vector $x''$ which is identical to $x$ except that $x''_{u_1} = 1$ is feasible to LP($I$). Now note that $x'$ is a convex combination of $x$ and $x''$. Hence, the claim follows.

We now prove the second statement. Since $x''_{u} \leq x_{u} + \epsilon$, we get that

\[
\text{val}(I, x') = \sum_{u} w_u x''_u \leq \sum_{u} w_u x_u + \epsilon \sum_{u} w_u = \text{val}(I, x) + \epsilon.
\]

$\square$
6.3 Details of Section 4.1

We prove Lemma 4.6 which is restated below.

**Lemma 6.2.** Let \( A \) be a upward monotone subset of \([0, 1]^k\) and let \((x_1, x_2, \ldots, x_k) \in \text{ConvexHull}(A)\) such that each \( x_i \) is an integral multiple of \( \epsilon \) (assume that \( 1/\epsilon \) is an integer). Then, there is a distribution \( P \) over \( A \) such that the minimum probability of any atom in \( P \) is at least \( \frac{\epsilon}{2^k} \).

**Proof.** We define a variable \( \lambda_r \) for every \( r \in A \). We want to find a solution to the following:

\[
\forall j \in \{1, \ldots, k\} \quad \sum_{r \in A} \lambda_r \sigma_{uj} = x_{uj} \quad (7)
\]

\[
\sum_{r \in A} \lambda_r = 1 \quad (8)
\]

\[
\forall r \in A \quad \lambda_r \geq 0 \quad (9)
\]

We know that there is a feasible solution to this set of constraints. A vertex solution corresponds to the unique solution obtained by subset of the constraints (where inequality is replaced by equality). For such a system of equations, \( A \cdot \lambda = b \), we observe that all entries in \( A \) are 0-1 and all entries in \( b \) are integral multiples of \( \epsilon \). The determinant of \( A \) is at most \( 2^k \). The value of \( \lambda_r \) (by Cramer’s rule) is the ratio of determinants of two matrices – the matrix \( A \) with one of the columns replaced by \( b \), and the matrix \( A \). Since each entry of \( b \) is a multiple of \( \epsilon \), it is easy to check that the determinant of the former matrix is either 0 or at least \( \epsilon \). This implies the lemma. \( \square \)

6.4 Details of Dictatorship Function (Section 4.2)

We give a brief introduction to the invariance principle in this section. Then we complete the soundness analysis (Theorem 4.10) of the dictatorship function by giving proof of Fact 4.11.

6.4.1 Gaussian Spaces and Mossel’s Invariance Principle

**Measure Spaces.** We will be concerned with real valued functions in two measure spaces.

1. *p-biased measure space.* For \( p \in [0, 1] \), the p-biased measure on \([0, 1]^r\) is denoted by \( \mu_p \) where for \( x = (x_1, \ldots, x_r) \in [0, 1]^r \), \( \mu_p(x) \) is defined as \( p^{|\{x_i=1\}|}(1-p)^{|\{x_i=0\}|} \). For \( f, g : \{0, 1\} \mapsto \mathbb{R} \), define the following inner product: \( \langle f, g \rangle_p := E_{x \sim \mu_p}[f(x)g(x)] \).

2. *Gaussian measure space.* We will denote by \( \gamma \) as the Gaussian measure on \( \mathbb{R}^r \) with density \( \gamma(x) := (2\pi)^{-r/2}e^{-\|x\|^2/2} \) for \( x \in \mathbb{R}^r \). For a function \( f : \mathbb{R}^r \mapsto \mathbb{R} \) we will denote by \( E_f[f] := \int_{\mathbb{R}^r} f(x)\gamma(x)dx \). We will restrict ourselves to \( f \in L^2(\mathbb{R}^r, \gamma) \), i.e., \( f \) such that \( E_f[f^2] < \infty \). For \( f, g : \mathbb{R}^r \mapsto \mathbb{R} \), define the following inner product: \( \langle f, g \rangle_\gamma := E_{x \sim \gamma}[f(x)g(x)] \).

**Gaussian stability.** For \( \rho \in [-1, 1] \), we denote by \( U_\rho \) the Ornstein-Uhlenbeck operator \( U_\rho \) which acts on \( L^2(\mathbb{R}^r, \gamma) \) as \( U_\rho f(x) \) is defined as \( E_{\rho \gamma}[f(\rho x + \sqrt{1-\rho^2} y)] \). It is easy to see that \( E_{\gamma}[U_\rho f] = E_{\gamma}[f] \). For \( 0 \leq \mu \leq 1 \), let \( F_\mu : \mathbb{R} \mapsto \{0, 1\} \) denote the function \( F_\mu(x) = 1_{\{x \leq \mu\}} \), where \( \mu \) is chosen in a way such that \( E_\gamma[F_\mu] = \mu \).

**Definition 6.3.** Given \( \mu, \nu \in [0, 1] \) and \( \rho \in [-1, 1] \), define

\[
\Gamma_\rho(\mu, \nu) \overset{\text{def}}{=} \langle F_\mu, U_\rho(1 - F_{1-\nu}) \rangle_\gamma.
\]

For a vector \((\rho_1, \rho_2, \ldots, \rho_{k-1}) \in [-1, 1]^{k-1}\) and \( \mu_1, \mu_2, \ldots, \mu_k \) we recursively define

\[
\Gamma_{(\rho_1, \rho_2, \ldots, \rho_{k-1})}(\mu_1, \mu_2, \ldots, \mu_k) \overset{\text{def}}{=} \Gamma_{\rho_1}(\mu_1, \Gamma_{(\rho_2, \ldots, \rho_{k-1})}(\mu_2, \ldots, \mu_k)).
\]

When the \( \rho_i \) are all equal to \( \rho \), and the \( \mu_i \) are all equal to \( \mu \), we will use \( \Gamma_\rho^k(\mu) \) to denote the term on left hand side above.

We will also need the following simple facts.

**Fact 6.4.** For every \( \theta \in (0, 1) \) and \( \rho = 1 - \lambda \in (0, 1) \), \( \Gamma_\rho(\theta, \theta) \geq \theta^{\lceil \lambda \rceil} \).

We use the above fact iteratively to obtain the following bound.

**Fact 6.5.** For every \( \theta \in (0, 1) \) and \( \rho = 1 - \lambda \in (0, 1) \), \( \Gamma_\rho^k(\theta) \geq \theta^{\lceil \lambda \rceil} \).
Product Spaces and Influences. Let $(\Omega^1, \mu_1), \ldots, (\Omega^r, \mu_r)$ be probability spaces and let $(\Omega, \mu)$ denote the product space $(\prod_{i=1}^{r} \Omega^i, \prod_{i=1}^{r} \mu_i)$. Let $f = (f_1, \ldots, f_k) : \Omega \mapsto \mathbb{R}^k$. The influence of the $i$-th coordinate on $f$ is defined as

$$\text{Inf}_i(f) \equiv \sum_{j,:,:k} \mathbb{E}_{x=(x_1, \ldots, x_r)} \left[ \text{Var}_{\mu_i} [f_j(x)|x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_r] \right].$$

Here, fixing $(x_1, \ldots, x_{i-1})$ and $(x_{j+1}, \ldots, x_r)$, $f_j(x)$ is just a function of $x_i$, call it $g$. Hence, the variance $\text{Var}_{\mu_i} [g] \equiv \mathbb{E}_{\mu_i} [g^2] - (\mathbb{E}_{\mu_i} [g])^2$. When $\Omega^1 = \cdots = \Omega^r$ and $f$ is a boolean function, let $(f_2^n : S \subseteq \{0, 1\}^r)$ denote the Fourier coefficients of $f$ with respect to the product measure $\mu$. Define the degree-$d$ influence of the $i$-th coordinate on $f$, $\text{Inf}_i^d(f)$, as $\sum_{j,:,:k} \mathbb{E}_{x=(x_1, \ldots, x_r)} f_j(x)$. We now give the proof of Fact 6.4.2 Completing the soundness proof of dictatorship function.

**Theorem 6.9**. Let $\rho(\mu) \equiv \sup \{|f, g| : f \in A, g \in B, \text{Var}_\mu[f] = \text{Var}_\mu[g] = 1\}$. Then if $G$ is connected then $\rho(\Omega^1, \Omega^2; P) \leq 1 - \alpha^2 / 2$.

**Theorem 6.11** (Invariance Principle). Let $(\prod_{i=1}^{k} \Omega^i, P^i)$, $1 \leq i \leq r$ be a sequence of correlated probability spaces such that for all $1 \leq i \leq r$ the minimum probability of any atom in $\prod_{j=1}^{i} \Omega^j$ is at least $\alpha$ . Assume furthermore that there exists $\rho \in [0, 1]^{k-1}$ and $0 \leq \rho_0 < 1$ such that $\rho(\Omega^1, \ldots, \Omega^k; P) \leq \rho_0$ and $\rho(\Omega^1, \ldots, \Omega^k; P) \leq \rho_j$ for all $i, j$. Then for all $\eta > 0$ there exists $\tau > 0$ such that if $f_j : \prod_{i=1}^{k} \Omega^i \rightarrow [0, 1]$ for $1 \leq j \leq k$ satisfy $\text{max}_{i,j} (\text{Inf}_i(f_j)) \leq \tau$ then

$$\Gamma_{\rho}(\mathbb{E}[f_1], \ldots, \mathbb{E}[f_k]) - \eta \leq \mathbb{E} \left[ \sum_{j=1}^{k} f_j \right].$$

One may take $\tau = \eta^{O(\log \log (1 / \epsilon) / \log(1 / \eta))}$.

### 6.4.2 Completing the soundness proof of dictatorship function

We now give the proof of Fact 4.11 which will complete the proof of Theorem 4.10. We first state the statement of this Fact below.

**Fact 6.10**. $\mathbb{E} \left[ \Pi_{uvR^c} f_{B(u)}^S (z(u)) \right] > 0$.

**Proof.** Let $\alpha \equiv \frac{\beta}{2 \beta}$ and $Q_e \equiv M_\beta(P_e^v)$. We know that the minimum probability of any atom in $Q_e$ is at least $\alpha$. Using Lemma 6.11 proved below, we have that the correlated space induced by $Q_e$ on $R_e$ has correlation at most $1 - \alpha^2$. Finally, using Fact 6.5, we know that the quantity $\Gamma_{\rho}(\delta, \ldots, \delta)$ is at least $\alpha^{(d^2 \alpha)^v} \equiv \beta$. Thus, using Theorem 6.9 with $\eta = \beta / 2$, we obtain $\tau = \tau(\eta)$ and $d = d(\eta)$ such that if for every $i$, $\text{Inf}_i^d(f^S_j) \leq \tau$, then

$$\mathbb{E} \left[ \Pi_{uvR^c} f_{B(u)}^S \right] \geq \beta - \beta / 2 \geq \beta / 2 > 0.$$
It remains to prove the following lemma.

**Lemma 6.11.** Consider an edge \( e = (u_1, u_2, \ldots, u_k) \in E \). Let \( \Omega_i \) denote the set \( \{0, 1\} \), \( i = 1, \ldots, k \). Let \( S_1, S_2 \) be two non-empty disjoint subsets of \( \{u_1, u_2, \ldots, u_k\} \). Then the correlated space induced by \( Q_e \) on \((x_{e \in S_1}, \Omega_1) \times (x_{e \in S_2}, \Omega_2)\) has correlation at most \( 1 - \left( \frac{\varepsilon}{2^k} \right)^2 \).

**Proof.** Let \( U \) denote the set \( S_1 \cup S_2 \). Let \( Q_1^2, Q_2^2, Q_U \) be the distributions obtained by restricting \( Q_e \) to \( S_1, S_2 \) and \( U \) respectively. Let \( \Omega_i \) denote the elements in \( x_{e \in S_i}, \Omega_i \) with non-zero probabilities associated by \( Q_i^2 \). Define \( \Omega_U \) similarly. Construct a bipartite graph on \( \Omega_S \times \Omega_U \) where we have an edge \((a, b)\) if \( Q_U^2((a, b)) > 0 \). We now argue that this graph is connected. Indeed, let \( a \in \Omega_S^2 \) and \( b \in \Omega_U^2 \). Since \( Q_U^2((a, b)) > 0, (a, 1) \) is an edge in this graph, where \( 1 \) is the all 1 vector of the appropriate dimension. Similarly, \((1, b)\) and \((1, 1)\) are edges in this graph. It follows that the vertices \( a \) and \( b \) are connected. Note that for every edge \((a, b)\) in this graph, \( Q_U^2((a, b)) \geq \frac{\varepsilon}{2^k} \). We now invoke Lemma 6.8 to finish the proof. \( \square \)

### 6.5 The Reduction

In this section, we give the reduction from **Unique Games** to a problem \( \Pi \) in the class \( k\text{-sm-CSP} \). We first state the version of **UGC** on which our results rely.

**Definition 6.12 (Unique Games).** An instance \( U = (G(U, A), [r], [\pi_e]_{e \in A}, wt) \) of **Unique Games** is defined as follows: \( G = (U, A) \) is a bipartite graph with set of vertices \( U = U_{\text{left}} \cup U_{\text{opt}} \) and a set of edges \( A \). For every edge \( e = (v, w) \in E \) with \( v \in U_{\text{left}}, w \in U_{\text{opt}} \), there is a bijection \( \pi_e : [r] \mapsto [r] \), and a weight \( wt(e) \in \mathbb{R}_{\geq 0} \). We assume that \( \sum_{e \in E} wt(e) = 1 \). The goal is to assign one label to every vertex of the graph from the set \([r]\) which maximizes the weight of the edges satisfied. A labeling \( \Lambda : U \mapsto [r] \) satisfies an edge \( e = (v, w) \), if \( \Lambda(w) = \pi_e(\Lambda(v)) \).

The following notations will be used in the hardness reduction and we state them here.

**Notations.**

1. For a vertex \( v \in U \), \( \Gamma(v) \) is the set of edges incident to \( v \).

2. For a vertex \( v \in U \), define \( p_e \overset{\text{def}}{=} \sum_{e \in \Gamma(v)} wt(e) \). This gives a probability distribution over the vertices in \( U_{\text{left}} \) (or \( U_{\text{opt}} \)).

We now state the Strong -UGC which was shown by Khot and Regev (KR08) to be equivalent to the **UGC** (Kho02).

**Conjecture 6.13 (Strong UGC).** For every pair of constants \( \eta, \zeta > 0 \), there exists a sufficiently large constant \( r \overset{\text{def}}{=} r(\eta, \zeta) \), such that it is **NP-hard** to distinguish between the following cases for an instance \( U = (G(U, A), [r], [\pi_e]_{e \in A}, wt) \) of **Unique Games**:  

- **YES:** There is a labeling \( \Lambda \) and a set \( U_0 \subseteq U_{\text{left}} \) of vertices, \( \sum_{u \in U_0} p_u \geq (1 - \eta) \), such that \( \Lambda \) satisfies all edges incident to \( U_0 \).

- **NO:** There is no labeling which satisfies a set of edges of total weight value more than \( \zeta \).

Now we describe the reduction from **Unique Games** instance to our problem. The reduction shall use the instance \( \mathcal{D} \) of \( \Pi \) produced by \( \text{Dict}^{\mathcal{D}}_{\mathcal{I}, \text{opt}}(r, \delta) \). Here \( x \) is the \( \varepsilon \)-perturbed solution corresponding to an optimal solution \( x^* \) to \( \text{lp}(\mathcal{I}) \).

**Input Instance :** The input to the reduction is an instance \( U = (G(U, A), [r], [\pi_e]_{e \in A}, wt) \) of **Unique Games** problem as defined in Definition 6.12. Recall that \( G \) is a bipartite graph with \( U = U_{\text{left}} \cup U_{\text{opt}} \), and the edge weights \( wt \) induce probability distribution \( p_e \) over vertices in \( U_{\text{left}} \).

**Output Instance :** The output instance \( \mathcal{F} \) of \( \Pi \) is as follows:

1. **Vertex Set** \( V(\mathcal{F}) = U_{\text{left}} \times V(\mathcal{D}) \), i.e., we place a copy of \( V(\mathcal{D}) \) at each vertex of \( U_{\text{left}} \). We shall index a vertex by \((u, b, y)\) where \( u \in U_{\text{left}} \) and \((b, y) \in V(\mathcal{D}) \).

2. **Vertex Weights** The weight of a vertex \((u, b, y)\) is \( w_{\mathcal{F}}((u, b, y)) = p_u \cdot w_{\mathcal{D}}(b, y) \).

3. **Hyper-edges** For every hyperedge \( e = (b^1, y^1), (b^2, y^2), \ldots, (b^k, y^k) \) in \( \mathcal{D} \), we add the following edges to \( \mathcal{F} \) – for each vertex \( u \in U_{\text{opt}} \) and all sets of \( k \) neighbors, \( u^1, \ldots, u^k \) (with repetition) of \( u \), we add the hyperedge \((u^1, b^1, y^1 \circ \pi^u_{(u^1, a^1)}), \ldots, (u^k, b^k, y^k \circ \pi^u_{(u^k, a^k)})\) to \( \mathcal{F} \). The constraint for these edges is the same as that for \( e \).
Suppose there is a labeling $\lambda$ for $\mathcal{U}$ and a subset $U_0$ of $U_{\text{un}}, \sum_{u \in U_0} p_u \geq 1 - \eta$, such that $\lambda$ satisfies all edges incident on $U_0$. Then there is a subset of vertices in $\mathcal{F}$ which satisfy all the constraints in $\mathcal{F}$ and has weight at most $lp(I) + \delta + \varepsilon + \eta$.

Proof. Consider the labeling $\lambda$. We now show how to pick a set $F$ of vertices from $V(\mathcal{F})$ which satisfies all the hyperedge constraints. For each $u \in U_0$, define $J_u$ as $\{(u, b, y) \in V(\mathcal{F}) : y_u = 1\}$. For each $u \in U_{\text{un}} - U_0$, define $J'_u$ as the set $\{(u', b', y') \in V(\mathcal{F}) : u' = u\}$. Now define $F = \bigcup_{u \in U_0} J_u \cup \bigcup_{u \in U_{\text{un}} - U_0} J'_u$.

We now show that $F$ satisfies all hyperedge constraints. Fix a hyperedge $e = \{(b^1, y^1), \ldots, (b^k, y^k)\}$ in $\mathcal{D}$. Let $u \in U_{\text{ign}}$ and $u^1, \ldots, u^k$ be $k$ neighbors of $u$. Consider a corresponding edge $f = \{(u^1, b^1, y^1 \circ \pi^u_{(u,w)}), \ldots, (u^k, b^k, y^k \circ \pi^u_{(u,w)})\}$ in $\mathcal{F}$. Lemma 4.9 shows that the set $C_i = \{(b, z) : z_i = 1\}$ satisfies the edge constraint for $e$ for any $i$. Let us pick $i = \lambda_u$. It will be enough to prove that if $(b^i, y^i)$ satisfies $y^i_1 = 1$, then the vertex $w = (u', b^i, y^i \circ \pi^u_{(u,w)})$ is in $F$. But this is indeed the case because if $u' \in U_0$, then $\lambda_u = \pi^u_{(u,w)}(\lambda_u)$. Therefore, $y^i \circ \pi^u_{(u,w)}$ has coordinate $\lambda_u$ equal to 1. Hence, $w \in J_u'$. If $u' \in U_{\text{un}} - U_0$, then we add $w \in J_u'$ trivially. Thus, we have shown that $F$ satisfies the edge constraint for the hyperedge $f$.

Let us now compute the weight of $F$. If $u \in U_0$, then Lemma 4.9 and Fact 3.2 show that the weight of $J_u$ is at most $p_u \cdot (lp(I) + \delta + \varepsilon)$. If $u \notin U_0$, then the weight of $J'_u$ is $p_u$. Thus, the weight of $F$ is at most

$$(lp(I) + \delta + \varepsilon) \sum_{u \in U_0} p_u + \sum_{u \in U_{\text{un}}} p_u \leq lp(I) + \delta + \varepsilon + \eta.$$ 

\[\square\]

**Soundness.**

**Theorem 6.15.** Suppose there is a subset of vertices $\mathcal{F}$ which satisfies all the constraints in $\mathcal{F}$ and $w_F(F) < \text{round}(I, x^*., \varepsilon) - 2\delta$. Then there is a constant $\zeta(\varepsilon, \delta, k)$ such that there is a labeling for $\mathcal{U}$ for which the set of satisfied edges has weight at least $\zeta(\varepsilon, \delta, k)$.

Proof. Consider a set $F$ satisfying the conditions of the theorem. Let $I_F(\cdot)$ be the indicator function for $F$. For a vertex $u \in U_{\text{ign}}$, let $N(u) \subseteq U_{\text{un}}$ denote the neighbors of $u$. Recall that every vertex of $\mathcal{F}$ can be written as $(w, z)$, where $w \in U_{\text{un}}$ and $z \in V(\mathcal{D})$. Since the distribution $\{p_u\}_{u \in U_{\text{un}}}$ is same as first picking a vertex $u \in U_{\text{ign}}$ with probability $p_u$ and then picking a random neighbor of $u$ (according to edge weights), we get

$$w_F(F) = E_{u \in U_{\text{ign}}} E_{w \in N(u)} E_{z \in V(\mathcal{D})} I_F((w, z \circ \pi^u_{(u,w)})),$$

where $z$ is picked according to vertex weights in $\mathcal{D}$. For a vertex $u \in U_{\text{ign}}$, let $G(u)$ denote the quantity $E_{w \in N(u)} E_{z \in V(\mathcal{D})} I_F((w, z \circ \pi^u_{(u,w)}))$.

We can therefore state the condition of the Theorem as $E_{u \in U_{\text{ign}}} G(u) < \text{round}(I, x^*., \varepsilon) - 2\delta$. Call a vertex $u \in U_{\text{ign}}$ good if $G(u) < \text{round}(I, x^*., \varepsilon) - \delta$. A simple averaging argument shows that the weight of good vertices is at least $\delta/2$.

Fix a good vertex $u$. Let $\mathcal{D}^{(u)}$ be a copy of the instance $\mathcal{D}$. We construct a solution $S^{(u)}$ for $\mathcal{D}^{(u)}$ as follows: for each $(b, y) \in V(\mathcal{D}^{(u)})$, we pick a random neighbor $u'$ of $u$ according to edge weights $w$ in the instance $\mathcal{U}$. If $(u', b, y \circ \pi^u_{(u,w)}) \in F$, we add $(b, y)$ to $S^{(u)}$.

**Claim 6.16.** $S^{(u)}$ satisfies all the constraints in $\mathcal{D}^{(u)}$.

Proof. Let $e = \{(b^1, y^1), \ldots, (b^k, y^k)\}$ be a hyperedge in $\mathcal{D}^{(u)}$. Suppose while constructing the set $S^{(u)}$, we decide to add $(b^i, y^i)$ to this set based on whether $(u^i, b^i, y^i \circ \pi^u_{(u,w)}) \in F$. Now observe that the instance $\mathcal{F}$ has the hyperedge $\{(u^1, b^1, y^1 \circ \pi^u_{(u,w)}), \ldots, (u^k, b^k, y^k \circ \pi^u_{(u,w)})\}$. Since this hyperedge is satisfied by $F$, the claim follows. \[\square\]

Note that $E[S^{(u)}]$ is exactly $G(u)$, where the expectation is over the choice of random neighbors of $u$. For each vertex $w \in U_{\text{un}}$ and $b \in [m]$, define a 0-1 function $f^{F, w}_{b, \varepsilon}$ on $[0, 1]^r$ as follows

$$f^{F, w}_{b, \varepsilon}(y) \overset{\text{def}}{=} \begin{cases} 1 & \text{if } (w, b, y) \notin F \\ 0 & \text{otherwise} \end{cases}$$
Note that $f^F_b$ is the indicator function for complement of $F$ for the set of vertices \{$(w, b, y) : y \in \{0, 1\}$\}. For the vertex $u$, we now define the function $f^F_u(y)$ which is the average of the corresponding functions for the neighbours of $u$.

\[ f^F_u(y) \equiv \frac{1}{\mathbb{E}} \sum_{w \in N(u)} f^F_b(y \circ \pi^u_{(u,w)}) . \]

Observe that $f^F_u(y) = \mathbf{P}(u, b, y) \not\in S(u)$, where the probability is over the choice of $S(u)$. Rest of the proof is very similar to the proof of Theorem 4.10 – the goal would be to prove the following statement:

**Lemma 6.17.** There exist values $b \in [m], i \in [r]$ and constants $d, \tau$ depending on $\delta$ and $k$ only such that $\ln f^F_b \geq \tau$.

**Proof.** Let $\tau$ and $d$ be as in the proof of Fact 4.11. Suppose, for the sake of contradiction, that the statement of the lemma does not hold for these values of $\tau$ and $d$. Define

\[ f(u) \equiv \mathbb{E} \left[ b \mid \mathbb{E} f^F_u(z) \leq \delta \right] . \]

Let $T^{(a)}_j \equiv \cup_{b \in \Pi} (b, [0, 1]^r)$. Fix a particular hyperedge $e = (a_1, a_2, \ldots, a_k) \in E$ of the instance $I$ (which gets used in $\mathbb{D}^{I_1}_{\epsilon, \delta} \equiv (r, \delta)$). Let

\[ R_e^{(a)} \equiv \{a_i \in e \mid B(a_i) \not\in f^{(u)} \} . \]

The following fact can be deduced in the same manner as the proof of Theorem 4.11.

**Fact 6.18.**

\[ \mathbb{E} \mathbb{P} \left[ b \in R_e^{(a)} \mid f^F_u(z) \geq \delta \right] > 0, \]

where the expectation is over the choice of $z^{(a)}$ from $q_B^{(a)}$-biased measure on $[0, 1]^r$.

Fact 6.18 implies that there exist neighbors $u^a \in N(u)$ for each $a \in R_e^{(a)}$ such that

\[ \mathbb{E} \mathbb{P} \left[ b \in R_e^{(a)} \mid f^F_u(z) \geq \delta \right] > 0. \]

Therefore, there exist values $\{z^{(a)} : a \in R_e^{(a)}\}$, such that $f^F_u(z^{(a)}) \circ \pi^u_{(u,a^e)} \equiv 1$ for all $a \in R_e^{(a)}$. But then consider the following choice of $S^{(a)}$: while considering $(B(a), z^{(a)})$, we pick the neighbor $u^a$ of $u$. Therefore, the set $S^{(a)}$ does not contain any element from the set $\{B(a), z^{(a)} : a \in R_e^{(a)}\}$. The set $S^{(a)}$ still satisfies all the constraints in $\mathbb{D}^{(a)}$ (Lemma 6.16). Hence, there exists a hyperedge $\{z^1, z^2, \ldots, z^k\}$ in $\mathbb{D}^{(a)}$ corresponding to $e$ which gets satisfied by $T^{(a)}_j$ only. Thus, all hyperedges in $\mathbb{D}^{(a)}$ are satisfied by $T^{(a)}_j$. But $w_{\mathbb{D}}(T^{(a)}_j) \geq \mathbb{P}(I, x^*, \varepsilon)$. Further, we know that

\[ \mathbb{E} w_{\mathbb{D}}(S^{(a)}) = G(u) \geq w_{\mathbb{D}}(T^{(a)}_j) - \delta. \]

This contradicts the fact that $\mathbb{E} w_{\mathbb{D}}(S^{(a)}) < \mathbb{P}(I, x^*, \varepsilon) - \delta$. Hence, the lemma is true.

The rest of the argument to complete the theorem follows standard arguments, see e.g. [Rag08].

**Choice of Parameters and Proof of Theorem 1.1** Given parameters $\varepsilon$ and $\delta$, and a constant value $k$, we first pick $\eta$ according to the proof of Fact 4.11 described in Section 6.4.2. The parameter $\eta$ can be assumed to be much less than $\delta$ (otherwise we can just set $\eta$ to be $\delta$). This yields the parameters $\tau$ and $d$ as specified by Lemma 6.17. Then, as in [Rag08], $\varepsilon(\delta, k)$ mentioned in the statement of Theorem 6.15 depends on $\tau, d, \delta$, and hence, on $\varepsilon, \delta$ and $k$ only. Now we pick the label size $r$ of the Unique Games instance $\mathcal{U}$ to be large enough such that we get a gap of $1 - (\eta + \varepsilon + \delta)$ versus $\varepsilon$ in the UGC. Theorems 6.14 and 6.15 now imply Theorem 1.1 if we pick the values $\delta$ and $\varepsilon$ in the reduction to be half of the ones mentioned in the theorem.
6.6 Strict Monotone Packing Constraint Satisfaction Problems

In this section, we show how our results can be framed in the setting of packing problems. We begin by defining the notion of downward monotone sets, and then show how this can be used to define analogous packing problems.

Given distinct \( x, y \in [0, 1]^k \), we say \( y \leq x \), if for every \( i \in [k] \), \( y_i \leq x_i \). Further, a subset \( A \subseteq [0, 1]^k \) is said to be downward monotone if for every \( x \in A \), and every \( y \) such that \( y \geq x \), it follows that \( y \in A \).

**Definition 6.19** (The class Packing-\( k \)-sm-CSP). Let \( k \) be a positive integer. An instance of type Packing-\( k \)-sm-CSP is given by

\[
\mathcal{I} = (V, E, \{A_e\}_{e \in E}, \{w_e\}_{e \in V})
\]

where:

- \( V = \{v_1, v_2, \ldots, v_n\} \) denotes a set of variables/vertices taking values over \( [0, 1] \) along with non-negative weights such that \( \sum_{v \in V} w_i = 1 \).
- \( E \subseteq V^k \) denotes a collection of hyperedges, each on at most \( k \) vertices. For each hyperedge \( e \in E \), there is a constraint \( A_e \) which is a downward monotone set denoting the set of accepted configurations of the vertices in \( e \).

The objective is to find an assignment \( \Lambda : V \rightarrow [0, 1] \) for the vertices in \( V \) that maximizes

\[
\sum_{v \in V} w_v \Lambda(v)
\]

such that for each \( e = (v_1, v_2, \ldots, v_k) \), \((\Lambda(v_1), \ldots, \Lambda(v_k)) \in A_e \).

**Definition 6.20** (A Packing-\( k \)-sm-CSP Problem). A Packing-\( k \)-sm-CSP problem \( \Pi \) is given by downward monotone sets \( \{A_1, \ldots, A_r\} \). Every instance of \( \Pi \) is supposed to have its constraints for the hyperedges to be one of \( \{A_1, \ldots, A_r\} \).

As in the case of \( k \)-sm-CSP, we can also define an analogous LP relaxation for any problem in the class Packing-\( k \)-sm-CSP. The LP is given in Figure 4. As before, for an instance \( \mathcal{I} \), let \( \text{lp}(\mathcal{I}) \) denote the optimum of the LP of Figure 4 for \( \mathcal{I} \). Also,

\[
\text{lp}(\mathcal{I}) = \text{maximize} \quad \sum_{e \in E} w_e x_e \\
\text{subject to} \quad \forall e = (v_1, v_2, \ldots, v_k) \in E \quad (x_{v_1}, x_{v_2}, \ldots, x_{v_k}) \in \text{ConvexHull}(A_e) \quad (12) \\
\forall e \in E \quad 0 \leq x_e \leq 1 \quad (13)
\]

Figure 4: LP for Packing-\( k \)-sm-CSP

let \( \text{opt}(\mathcal{I}) \) denote the value of the optimal integral solution for \( \mathcal{I} \). As we argued for the (covering) \( k \)-sm-CSP, the program above can indeed be written as an LP. Also, for the INDEPENDENT SET and HYPERGRAPH INDEPENDENT SET problems, the LP above happens to be at least as strong as the natural LP’s for these problems.

**Main Theorem for Packing-\( k \)-sm-CSP.** We now state the analogue of Theorem 1.1 for Packing-\( k \)-sm-CSP. We shall describe a rounding algorithm, ROUND-PACK for the LP of Figure 4. For an instance \( \mathcal{I} \) of \( \Pi \) we first compute \( x^* \), the optimal LP-solution for \( \mathcal{I} \). For a Packing-\( k \)-sm-CSP \( \Pi \) and a parameter \( \epsilon > 0 \), let ROUND-PACK(\( \mathcal{I} \), \( x^* \), \( \epsilon \)) denote the value of ROUND-PACK. The following theorem shows that, assuming the UGC, the rounding algorithm essentially gives the best approximation algorithm for \( \Pi \).

**Theorem 6.21.** Let \( \Pi \) be a Packing-\( k \)-sm-CSP, \( \epsilon > 0 \), and \( \mathcal{I} \) be an instance of \( \Pi \). Then for every \( \delta > 0 \), assuming the UGC, it is NP-hard to distinguish instances of \( \Pi \) with optimal more than \( \text{lp}(\mathcal{I}) - \epsilon - \delta \) from those with optimal less than \( \text{ROUND-PACK}(\mathcal{I}, x^*, \epsilon) + \delta \). Here \( x^* \) is the optimal LP solution for \( \mathcal{I} \).
The Rounding Algorithm

We now describe the rounding algorithm ROUND-PACK. We first define the notion of discretizing a solution $x$ as in Definition 3.1. We assume without loss of generality that the parameter $\varepsilon$ satisfies the condition that $1/\varepsilon$ is an integer.

Definition 6.22. Given a feasible solution $x$ to LP($I$) and a parameter $\varepsilon > 0$, define $x^\varepsilon$ as follows – for each $u \in V$, let $k_u$ be the integer satisfying $k_u \varepsilon \leq x_u < (k_u + 1)\varepsilon$.

The rounding algorithm is described in Figure 5.

**Figure 5: Algorithm ROUND-PACK**

| **INPUT:** | An instance $I = (V, E, \{A_e\}_{e \in E}, \{w_v\}_{v \in V})$ of a problem in Packing-$k$-sm-CSP, a feasible solution $x$ to LP($I$) and a parameter $\varepsilon > 0$. Let $m := 1/\varepsilon$. |
| **OUTPUT:** | A labeling $\Lambda : V \rightarrow \{0, 1\}$. |
| 1. | Construct the solution $x^\varepsilon$. |
| 2. | For every $z \in \{0, 1\}^m$, construct a 0-1 solution $\Lambda^z$ as follows : $\Lambda^z_u \overset{\text{def}}{=} z_j$ if $x^\varepsilon_u = j\varepsilon$. |
| 3. | Output the solution $\Lambda^z$ which has the largest objective value among all feasible solutions in $\{\Lambda^z | z \in \{0, 1\}^m\}$. |
