Abstract

Probabilistically-Checkable Proofs (PCPs) form the algorithmic core that enables succinct verification of long proofs/computations in many cryptographic constructions, such as succinct arguments and proof-carrying data.

Despite the wonderful asymptotic savings they bring, PCPs are also the infamous computational bottleneck preventing these cryptographic constructions from being used in practice. This reflects a lack of understanding of how to study and improve the concrete (as opposed to asymptotic) efficiency of PCPs.

We propose a new efficiency measure for PCPs (and its major component: locally-testable codes and PCPs of proximity). We define a concrete-efficiency threshold that indicates the smallest problem size beyond which the PCP becomes “useful”, in the sense that using it actually pays off relative to naive verification by simply rerunning the computation; our definition takes into account both the prover’s and verifier’s complexity.

We then show that there exists a PCP with a finite concrete-efficiency threshold. This does not follow from existing works on PCPs with succinct verifiers. We provide an explicit PCP construction where the prover and verifier are efficient enough to achieve a finite threshold, and further show that this PCP has the requisite properties for being used in the cryptographic applications mentioned above. Our construction in fact also yields a PCP system for random-access machines where the (asymptotic) time complexity of both the prover and verifier are essentially optimal and where both prover and verifier are highly-parallelizable.

Moreover, we extend and improve the Reed-Solomon PCPs of proximity over fields of characteristic 2, which constitute the main component in the quasilinear-size construction of [Ben-Sasson and Sudan, STOC ’05] as well as our construction. Our improvements reduce the concrete-efficiency threshold for testing proximity to Reed-Solomon codes from $2^{572}$ in their work to $2^{35}$, which is tantalizingly close to practicality. We hope this will motivate the search for even better constructions, ultimately leading to practical PCPs for succinct verification of long computations.

Keywords: PCPs; low-degree tests; Reed-Solomon code; verification of computation

1 Introduction

The study of probabilistically-checkable proofs (PCPs) was initiated by Babai et al. [BFLS91] and Feige et al. [FGL+96] with two very different motivations. Babai et al. focused on “positive” applications of PCPs: enabling succinct verification of long computations. On the other hand, Feige et al. focused on “negative” applications of PCPs: proving inapproximability results.

In this paper we initiate the study of practical PCPs, by which we mean the study of the concrete (as opposed to asymptotic) efficiency of PCPs, via cost functions that are informed by the efficiency concerns that arise in positive applications of PCPs. We present three contributions: the first is a definitional one, the remaining two are of a technical nature.

We introduce a definition for the concrete-efficiency threshold $B$ of a given PCP system $S$. Informally, $B$ is the smallest value $T$ for which using $S$ to verify computations of running time at least $T$ does in fact offer savings over naive verification (i.e., in which the prover writes down all $T$ steps of the computation and the verifier reads this transcript from start to end).

Our first result is that there exists a PCP system with finite concrete-efficiency threshold. As we shall argue, this is not the case for existing PCP constructions. We further show that our PCP construction has the requisite properties for use in cryptographic constructions like succinct interactive arguments of knowledge [Kil92, Mic00, Val08, BG08], succinct non-interactive arguments of knowledge (SNARKs) [BCCT11], and proof-carrying data [CT10, CT12].

As an intermediate step to computing the concrete-efficiency threshold of our PCP system (which is quite challenging), we study instead the concrete-efficiency threshold of the “heaviest” component in our construction: PCPs of proximity (PCPPs) for Reed-Solomon codes over fields of characteristic 2. These, as in [BSS08], lie at the heart of our PCP system. Using an improved analysis of these PCPPs we obtain our second result: a reduction in the concrete-efficiency threshold of PCPPs for Reed-Solomon codes from $2^{572}$ in [BSS08] to $2^{35}$.

The ultimate goal of our work is to make the vision of Babai et al. a reality via practical PCP implementations. The quest for practical PCPs reveals a mostly-uncharted landscape, whose exploration is an intriguing research direction that we believe will lead to interesting insights and techniques, with the potential of great impact in light of the many useful cryptographic constructions that crucially rely on PCPs.

1.1 Motivation

PCPs are the “verification engine” of many cryptographic protocols that enable various flavors of succinct verification of long computations, including succinct interactive arguments [Kil92, Mic00, BG08], succinct non-interactive arguments (SNARGs) [DCL08, BCCT11, DFH12, GLR11], and even proof-carrying data [CT10, CT12]. Unfortunately, PCPs are also the notorious computational bottleneck of all these cryptographic protocols: despite the great practical potential of succinct verification of long computations, any construction relying on PCPs is dismissed as impractical.

Theoretical results have already established the feasibility of succinct probabilistic verification of long computations [BFLS91, BS10+05, Mie09]: it is possible to encode a computation

\footnote{Proof-carrying data ensures local invariants of dynamic distributed computations. Special cases of proof-carrying data include the goals of incrementally-verifiable computation [Val08] and targeted malleability [BSW06].}

\footnote{See Appendix A for a summary of various flavors of solutions (and some implementations) for the problem of succinct verification of long computations.}
with only a polynomial (in fact, even quasilinear) blowup in length and then verify it in poly-
logarithmic time. However, these results are only asymptotic results. In fact, a lack of explicit
constructions, tight complexity analyses, and proof details currently make it difficult to even
assess how far current PCP constructions are from practical efficiency.

We believe that this situation should change: we should strive to understand the concrete
(rather than asymptotic) efficiency of PCPs and see how much such efficiency can be “pushed”
in an effort to realize the unfulfilled impact of one of the most beautiful results theoretical
computer science can claim.

1.2 Goals

Given a program $P$ (say, written in C++), an input $x$, and a time bound $T$, a verifier wishes to
check whether a witness $w$ causes $P(x, w)$ to accept within $T$ time steps. Without the help of a
prover, the verifier can only perform the naive verification procedure: run $P(x, w)$ for at most $T$
steps and check if it halts and accepts within that time.

As [BFLS91] showed, a PCP saves the verifier the cost of performing this naive verification
procedure, and enables instead a much faster succinct probabilistic verification procedure: a
PCP verifier can run in only $\text{poly}(|P|, |x|, \log T)$ time when having oracle access to a PCP proof
string $\pi$ of length $\text{poly}(|P|, |x|, T)$ generated by a PCP prover (who is also given $w$ as auxiliary input).
More recent works [BSGH+05, Mie09] achieved a PCP proof length $T \cdot \text{poly}(|P|, |x|, \log T)$.

As $T$ grows larger (and viewing $|x|$ as relatively small) the saving in running-time becomes more
dramatic, and at some point running the PCP verifier is much better than naive verification.

Two things complicate the matter. The first is that the known PCP constructions with succ-
cinct verifiers have huge overheads, indicating that real savings are made only for prohibitively
large $T$. The second complication is that the PCP prover must convert the computation-
transcript (which is of length $T$) into a PCP proof for the PCP verifier. This cost is at least as
large as the length of a PCP proof but — if not constructed by efficient algorithms — can be
much larger, so much so as to kill any prospect of using a PCP system in practical settings.

Therefore, the crucial parameters of interest from the point of view of using PCPs for succinct verification of long computations are the prover running time and the verifier running time.\(^3\) While clearly these times can be traded off against each other (e.g., increasing proof
length, and thus prover running time, enables the design of more “robust” tests with faster
verifiers), we want them instead to simultaneously be as short as possible. This sets the ground
for the basic question studied in this paper:

**Our Question:**

Can we design a definition that captures the concrete efficiency of a given PCP system?

Do there exist PCP systems with good concrete efficiency?

Such a definition could provide a new efficiency measure for the study of PCPs, one that is
different than other traditional efficiency measures (such as query and randomness complexity)
and better captures what we look for in a PCP that is to be used in positive applications, by
taking into account both the prover running time and verifier running time.

---

\(^3\) The running time of the verifier depends on the target soundness. Our convention is to consider a target
soundness of $1/\epsilon$; then, $k$-fold sequential repetition results in soundness $2^{-k}$ and a multiplicative blowup in running
time of $k$. (We are not interested in randomness-efficient repetition as in, e.g., [BSS08, Proposition 2.9].)
1.3 Summary of Our Results

(R1) Defining the concrete efficiency of a PCP system. We suggest to capture the concrete efficiency of a given PCP system by defining a concrete-efficiency threshold $B$ that indicates the problem size beyond which naive verification of a computation actually takes longer than using the PCP system; in other words, $B$ is the smallest problem size beyond which the PCP system always guarantees that using it is better than not using it.

To instantiate the above approach into a definition, we first need to agree on a meaningful cost function $C$. As already discussed in Section 1.2, the two parameters of interest are the prover running time (or, equivalently, proving overhead) and verifier running time. So we will let the cost function $C$ take these two as input in order to compute a combined cost, and then compare this cost against the cost of naive verification. More precisely, the concrete-efficiency threshold of a PCP system is the smallest problem size beyond which the (combined) cost output by $C$ is always smaller than a savings factor $\gamma$ times the cost of naive verification, for a given $\gamma \in (0, 1)$.

**Definition 1** (informal). A PCP system is $B$-efficient with respect to cost function $C$ and savings factor $\gamma$ if $B$ is the smallest integer for which every true statement $y$ of size at least $B$,

$$C\left(\text{PCP proving overhead for } y, \text{PCP verification time for } y\right) < \gamma \cdot C\left(\text{naive verification time for } y\right).$$

Depending on the application, different choices of cost function $C$ and savings factor $\gamma$ may be meaningful. In this paper, we choose $C(a, b) \overset{\text{def}}{=} a \cdot b$ and $\gamma \overset{\text{def}}{=} 1/2$ as a natural convention.

For concreteness, we need to choose a computational model (through which provers and verifiers will be represented) as well as a “reference” complete problem relative to which a given PCP is constructed. We choose circuits for both: our definition assumes that provers and verifiers are specified as Boolean circuits, and considers PCP systems constructed for the \textsc{NEXP}-complete language \textsc{Succinct Circuit Sat} (or sCSAT for short), which is the language of satisfiable circuits that are succinctly represented. These choices are not arbitrary: analogous alternative definitions for other choices are of course possible, but one must be careful.

Indeed, in moving from an asymptotic study of efficiency to a concrete one, we must be very explicit about how we model computation. For example, fixing an arbitrary universal Turing machine as a model computation will make the definition of $B$ meaningless: it could be that the universal Turing machine we fixed has all problems of size less than $2^{1000}$ precomputed, and would cause $B = 1$ for any PCP system that becomes useful just before $2^{1000}$. To avoid such problems, we would need to specify a “natural” universal Turing machine explicitly, but then we would have a tough choice about which one to pick. By choosing circuits, instead, we can be explicit about the model of computation without much work (e.g., by specifying a natural Boolean basis and settings for fan-in and fan-out).

Henceforth our goal is to construct $B$-efficient PCP systems for sCSAT with as small a $B$ as possible.

(R2) A PCP system with $B < \infty$. It is not clear that a PCP system with a finite efficiency threshold even exists, and such a system does not follow from previous works on the topic.

---

4Note that it is indeed essential to choose a language that gives the freedom to specify large constraint satisfaction problems succinctly: the verifier should not be forced to read a given constraint satisfaction problem in explicit form because then it would not have a chance to make any savings in running time!
Indeed, PCP constructions designed for inapproximability results (and most constructions fall under this category) have both prover and verifier running in time that is at least linear in $T$, and therefore have an infinite efficiency threshold of $\infty$ (i.e., none exists) [FGL+96, AS98, ALM+98, PS94, RS97, HS00, BSSW03, BSGH+04, GS06, Din07, BSS08, MR08, Mei12]. Turning to PCP constructions with succinct verifiers [BFLS91, BSGH+05, Mie09], these focus solely on the verifier’s running time, and none have studied the prover’s running time. Careful inspection of these works reveals that the running time can be bounded by a polynomial in $T$, but if this polynomial is quadratic (or larger) then, once again, the concrete-efficiency threshold is $\infty$.

Another issue is the dependence of the running time of the prover or verifier on the instance size: if it is more than quadratic, then again the concrete-efficiency threshold is $\infty$.

Our first main theorem is the construction of a PCP system for programs (more precisely, random-access machines [CR72, AV77]) where the time complexity of both the prover and verifier are essentially optimal (and where both prover and verifier are highly-parallelizable); in particular, we deduce that our definition of concrete efficiency can be fulfilled:

**Theorem 1** (informal). There is a PCP system where, to prove and verify that a program $P$ accepts the input $(x, w)$ within $T$ steps for some witness $w$ (with $|x|, |w| \leq T$),

**Sequential Time:**
- on input $(P, x, T, w)$, the prover runs in time $(|P| + T) \cdot \text{polylog}(T)$;
- on input $(P, x, T)$, the verifier runs in time $(|P| + |x|) \cdot \text{polylog}(T)$.

**Parallel Time:**
- the prover runs in parallel time $O((\log T)^2)$, when given as additional input the transcript of computation of $P$ on input $(x, w)$;
- the verifier runs in parallel time $O((\log T)^2)$.

In particular, there exists a PCP system for $s\text{CSAT}$ with concrete-efficiency threshold $B < \infty$.

Having established that it is indeed possible to obtain a finite concrete-efficiency threshold, we wish to carefully optimize our PCP construction from the proof of Theorem 1 with the goal of deriving as tight an analysis as possible to show a small value of $B$. Deriving an upper bound on $B$, however, would entail deriving concrete upper bounds on the size of fairly-complicated circuits implementing the prover and verifier. Such a computation seems infeasible without the aid of a full, working implementation. We propose instead a more tractable, yet still meaningful, approach to study $B$, which we describe next.

(R3) **Towards a small $B$: concrete efficiency of PCPP verifiers for Reed-Solomon.** Our PCP construction from the proof of Theorem 1 is an algebraic PCP whose technical heart, like other algebraic PCPs, is a low-degree test, where a verifier $V$ is given oracle access to a function $f$, and possibly also an auxiliary “proximity proof” $\pi$, and must test proximity of $f$ to some code of low-degree polynomials by querying $(f, \pi)$ at a few places.

A low-degree test is a special case of a PCP of Proximity (PCPP) system for a code ensemble and, in order to study the concrete efficiency of low-degree tests, we propose a definition (analogous to Definition 1) for the concrete efficiency of PCPP systems for code ensembles. In this new definition, instead of computing a combined cost based on the prover and the verifier running time, we compute a combined cost based on the length of the codeword plus its PCPP
proof (or, more precisely, blow up in this length relative to the dimension of the code) and the number of queries of the verifier.

**Definition 2** (informal). A PCPP system for a given code ensemble $\mathcal{E}$ is $\hat{B}$-efficient if $\hat{B}$ is the smallest integer for all $k \geq \hat{B}$

$$\left(\frac{n(k) + L(k)}{k}\right) \cdot Q(k) < \frac{1}{2} \cdot k$$

where $n(k)$ denotes the block-length, $L(k)$ the length of the PCPP proof generated by the prover, and $Q(k)$ the query complexity of the verifier for codes in $\mathcal{E}$ of dimension $k$.

The definition above is an “information-theoretic” version of Definition 1 as it disregards the computational cost of the prover for producing the proof and of the verifier for generating queries and examining answers, focusing on information-theoretic measures instead (cf. Remark 2.8).

As in [BSS08, BSGH+05], the relevant code ensemble for our PCP construction from the proof of Theorem 1 is the ensemble $\mathcal{E}_{RS}$ of Reed-Solomon (RS) codes evaluated over linear subspaces of fields of characteristic 2.\(^5\) let us denote $\hat{B}_{RS}$ the concrete-efficiency threshold of a given PCPP system for $\mathcal{E}_{RS}$. The advantage of the simpler Definition 2 is that we will be able to explicitly derive upper bounds for the $\hat{B}_{RS}$ of PCPP systems that we construct. The analysis of the PCPP system for Reed-Solomon in [BSS08] only shows an efficiency threshold of $\hat{B}_{RS} \leq 2^{572}$, which is an astronomical upper bound. Our second main theorem significantly improves on it and obtains a PCPP system with small(er) $\hat{B}_{RS}$:

**Theorem 2** (informal). There exists a PCPP system $\mathcal{E}_{RS}$ with $\hat{B}_{RS} \leq 2^{35}$.

Problem sizes on the order of $2^{35}$ are tantalizingly close to practicality! We are thus very optimistic about the prospect of improving further the concrete-efficiency thresholds of PCPP systems for Reed-Solomon codes and, thus ultimately, of algebraic PCPs.

While we only provide an upper bound on the information-theoretic (and thus weaker) efficiency measure of Definition 2 for the PCPPs we construct, doing so is still meaningful because we show that the algorithmic costs in our PCPP construction (and, ultimately, also in our PCP construction) only account for small additional logarithmic factors relative the PCPP proof length and query complexity; we thus expect $B$ to be not much larger than $\hat{B}_{RS}$. (For more details see **(R5)** below and Remark 2.10.)

**(R4) Properties of our PCP system for cryptographic constructions.** A PCP system is not used “as is” in positive applications, because one needs to somehow ensure that the verifier has oracle access to a fixed PCP string. Instead, the PCP system is plugged into cryptographic constructions that leverage the PCP soundness guarantees — but these constructions often require the PCP system to satisfy additional properties.

Possibly the most important positive application of PCPs is the construction of succinct arguments [Kil92, Mic00, BG08], because a practical succinct argument implies a practical delegation scheme for all of NP — a major open problem in cryptography. In fact, PCPs seem to be inherent to the construction of succinct arguments [RV09] and the efficiency of a succinct argument is usually closely related to the efficiency of the PCP used to construct it. (See Remark 11.3.)

\(^5\)More precisely, we shall work in the slightly more general setting of affine subspaces.
An example of an additional property that is often needed in constructions of succinct arguments is proof of knowledge; it gives, e.g., the ability to delegate “cryptographic computations” [BCCT11] and to recursively compose non-interactive proofs [Val08, CT10, BSW12, BCCT12, CT12]. It is required to construct computationally-sound proofs of knowledge in the random-oracle model [Mic00, Val08], SNARKs [BCCT11], and proof-carrying data [CT10, CT12].

Other times even more properties are needed. For example, the construction of universal arguments by Barak and Goldreich [BG08] requires, besides a variant of proof of knowledge, two other properties: a non-adaptive verifier and the existence of an efficient reverse sampler for the queries. The application of universal arguments is noteworthy as (together with the reductions in [Kil92, Mic00]) it is a succinct argument in the plain model whose security reduction relies on standard cryptographic assumptions (in contrast to the security reductions of the non-interactive succinct arguments in [Mic00, Val08, CT10, CT12] and [DCL08, BCCT11, DFH12, GLR11] that respectively rely on oracle and extractability assumptions).

Thus, when studying positive applications of PCPs, we must not only take into account the efficiency considerations that arise in practice (as discussed in Section 2.1), but also any additional properties that may be needed for using PCPs within a given cryptographic application.

Our third theorem states that our PCPs can be used in several cryptographic constructions:

**Theorem 3** (informal). The PCPs from Theorem 1 satisfy the requisite properties for the construction of a weaker (yet still useful) variant of universal arguments [BG08]. In particular, our PCPs also satisfy the requisite properties for the construction of computationally-sound proofs of knowledge [Mic00, Val08], SNARKs [BCCT11], and proof-carrying data [CT10, CT12].

Furthermore, due to the essentially-optimal running times of the PCP prover and verifier from the first part of our Theorem 1, we obtain the first constructions of the aforementioned cryptographic primitives such that the prover and verifier have essentially-optimal time complexity.

**Algorithmic specifications.** Beyond the theoretical results, we offer an additional technical contribution: our PCP construction (used in the proof of Theorem 1) includes a complete and detailed algorithmic specification of every non-elementary algorithm used by the verifier and the prover. This provides a reference for others wishing to study the concrete efficiency of PCPs.

The specification makes it clear how the various components of our construction come together, and how we leverage the computational properties of linearized polynomials [LN97, Section 2.5] in finite field extensions of \( \mathbb{F}_2 \) and additive-FFT methods [Mat08] for ensuring the efficiency properties of our construction. We also provide a detailed complexity analysis of the proof length, randomness, and query complexity. For more details see Appendix B and Appendix C.

2 Main Results

In this section we formally state our main results, discussed at high level in Section 1.3; along the way, we shall give pointers to the relevant technical sections. We start with the definition of the concrete-efficiency threshold of a PCP system (Section 2.1); we then state our first main result about the existence of a PCP system with finite concrete-efficiency threshold (Section 2.2); we then define the concrete-efficiency threshold for PCPPs and state our second main result about PCPPs for Reed-Solomon codes (Section 2.3); finally, we discuss cryptographic properties of the PCPs we construct (Section 2.4).
2.1 Defining the Concrete-Efficiency Threshold of a PCP System

In this section, we formalize our result (R1) by defining the concrete-efficiency threshold of a PCP system (which we informally introduced in Definition 1).

For simplicity, we use Boolean circuits with only NAND gates as our model of computation. A (Boolean) circuit $C$ is a directed acyclic graph with fan-in and fan-out equal to 2; its size is the number of vertices in this graph. If the graph has $n$ sources and $m$ sinks, then we say that the circuit has $n$ inputs and $m$ outputs. The circuit $C$ then computes a corresponding Boolean function $f_C$ from $\{0,1\}^n$ to $\{0,1\}^m$ in the natural way: the evaluation of an input $x \in \{0,1\}^n$ is performed by placing each bit of $x$ at the corresponding source of the graph (when taking sources, say, in lexicographic order) and then, by considering every non-source non-sink vertex as a NAND gate, a bit for each sink is computed by evaluating the circuit in some topological order; the output $y \in \{0,1\}^m$ is the string of bits at the sinks (when taken, say, in lexicographic order). The circuit $C$ is satisfiable if there is some input $x$ that makes the first bit of the output of $f_C(x)$ equal to 1. We assume a canonical representation of circuits as strings.

We also need to choose a “reference” complete language relative to which to construct PCPs. The language Succinct Circuit SAT (sCSAT for short) will be quite convenient; informally, sCSAT is the language of all satisfiable Boolean circuits $C$ over $2^n$ gates that are succinctly represented via a descriptor circuit $F$ having (roughly) $n$ inputs and $n$ outputs. Formally:

**Definition 2.1** (Succinct Circuit SAT [Pap94]). Let $n \in \mathbb{N}$, $f: \{0,1\}^{n+2} \rightarrow \{0,1\}^n$. The circuit corresponding to $f$, denoted $C_f$, is the circuit with $2^n$ gates, each labeled with an $n$-bit string, such that: for each gate $s \in \{0,1\}^n$, letting $s_00 = f(s00)$, $s_01 = f(s01)$, $s_{10} = f(s10)$, and $s_{11} = f(s11)$, gates $s_00$ and $s_{01}$ have wires going into $s$, and gate $s$ has wires going into $s_{10}$ and $s_{11}$; if $s = s_{00} = s_{01}$ then $s$ is an input gate; if $s = s_{10} = s_{11}$ then $s$ is an output gate. (And if $f$ $C_f$ is not “valid”, i.e. a gate receives more than two wires, then $C_f$ is the circuit with no wires.)

The language Succinct Circuit SAT, or sCSAT for short, is the language of all circuit descriptors $F$ such that the Boolean function $f$ computed by $F$ is of the form $f: \{0,1\}^{n+2} \rightarrow \{0,1\}^n$ and $C_f$ is satisfiable. (Note that we can assume without loss of generality that $|F| \leq 2^n$.)

Informally, a PCP system for sCSAT is a pair consisting of a prover $P$ and a verifier $V$ that works as follows. The prover receives as input a circuit descriptor $F$ describing a circuit $C$ and an assignment $w$ for $C$, and outputs a PCP proof $\pi$ for the claim “$w$ is a satisfying assignment of $C$”. The verifier receives as input the circuit descriptor $F$ and a string of random bits, and has two outputs: a set of indices (indicating the bits of the proof that are to be read) and a predicate (which decides whether the answers to the queries are satisfactory); we assume that the verifier is non-adaptive, i.e., all queries depend only on the input of the verifier and not on the answers provided by the prover. Because our computational model is circuits, $P$ and $V$ are represented as circuit families, each indexed by two integers $n$ and $k$ where, e.g., $P_{n,k}$ is the circuit that is “specialized” for descriptor circuits $F$ of size $k$ describing circuits of size $2^n$.

Thus, analogously to previous definitions of PCP systems (with succinct verifiers) [BFLS91, BSGH+05], we have the following definition:

**Definition 2.2** (PCP system for sCSAT). Let $P = \{P_{n,k}\}_{n,k\in\mathbb{N}}$ and $V = \{(Q_{n,k}, D_{n,k})\}_{n,k\in\mathbb{N}}$ be circuit families. We call $(P, V)$ a PCP system for sCSAT if the following conditions hold:

- Completeness. For every $(F, w)$ with $F: \{0,1\}^{n+2} \rightarrow \{0,1\}^n$ and $w$ is witness to $F \in \text{sCSAT}$,

$$\Pr_r \left[ D_{n,F}(r, F, \pi|q) = 1 \Bigg| \pi \leftarrow P_{n,F}(F, w), \bar{q} \leftarrow Q_{n,F}(r, F) \right] = 1, \right.$$

9
where $\vec{q}$ is interpreted as a vector of indices and $\pi|_{\vec{q}}$ is the substring of $\pi$ induced by $\vec{q}$.

- Soundness. For every $F: \{0,1\}^{n+2} \rightarrow \{0,1\}^n$ such that $F \notin \text{sCSAT}$ and every $\tilde{\pi}$,

$$\Pr_r \left[ D_{n,|F|}(r, F, \tilde{\pi}|_{\vec{q}}) = 1 \bigg| Q_{n,|F|}(r, F) \right] < \frac{1}{2}.$$ 

The following definition is the main notion motivating our work. Informally, given a PCP system $(P,V)$ for sCSAT, we define its concrete-efficiency threshold $B$ as the smallest $n$ such that, for every circuit $F$ describing a circuit $C$ of size at least $2^n$, when using the PCP system $(P,V)$ on input $F$ we save a multiplicative factor $\gamma = \frac{1}{2}$ over naive verification of $C$, when taking into account both proving overhead and verification time via the cost function $C(a,b) = a \cdot b$. (Recall that these choices of savings factor and cost function are the convention we fix in this paper.)

**Definition 2.3** (concrete-efficiency threshold for PCPs). Let $(P,V)$ be a PCP system for sCSAT (cf. Definition 2.2). The **concrete-efficiency threshold** of $(P,V)$ is the smallest integer $B$ such that for every circuit $F$ computing a Boolean function of the form $f: \{0,1\}^{n+2} \rightarrow \{0,1\}^n$ with $n \geq B$,

$$\left( \frac{|P_{n,|F|}|}{|F| \cdot 2^n} \right) \cdot (|Q_{n,|F|}| + |D_{n,|F|}|) < \frac{1}{2} \cdot (|F| \cdot 2^n).$$

(2)

If no such integer exists, the concrete-efficiency threshold of $(P,V)$ is infinite (i.e., $B := \infty$).

In the formal definition above we have instantiated the intuitive quantities that appeared in the informal Definition 1: given a circuit descriptor $F$ of size $k$ describing a circuit $C$ of size $2^n$ (which takes the role of the statement $y$),

- the naive verification time is given by $k \cdot 2^n$, because $C$ has $2^n$ gates and computing the input/output wires of each gate of $C$ requires evaluating $F$, of size $k$, on appropriate inputs;
- the prover overhead is given by $\frac{|P_{n,k}|}{k \cdot 2^n}$, because $|P_{n,k}|$ is the size of the appropriate prover divided by $k \cdot 2^n$, which again is the time to understand the topology of $C$; and
- the verification time is given by $|Q_{n,k}| + |D_{n,k}|$, because $|Q_{n,k}|$ and $|D_{n,k}|$ are the sizes of the appropriate query and decision algorithms.

**Remark 2.4.** The use of two parameters $n$ and $k$ in Definition 2.3 is necessary: omitting one of them would make Definition 2.3 satisifiable only with $B = \infty$. The is because a circuit of size $2^n$ can have a descriptor circuit that can itself be as large as $2^n$. Similarly, a descriptor circuit of size $k$ can describe a circuit of size between $k$ and $2^k$. If only one parameter is used, say $k$, we would need the verifier to be of size $2^k$ even though in some cases a circuit described by $k$ bits has size poly($k$). This would imply that no finite concrete-efficiency threshold exists.

### 2.2 Theorem 1: A $B$-efficient PCP for sCSAT with $B < \infty$

In this section, we formalize our result (R2) by restating our first main theorem, Theorem 1, more formally; its proof is given in Section 5.

Define BH$_{\text{RAM}}$ to be the language consisting of all triples $(M, x, T)$, where $M$ is a random-access machine (cf. [BSCGT12]), $x$ is an input, and $T$ is a time bound (with $|x| \leq T$), for which there exists a witness $w$ (with $|w| \leq T$) such that $M$ accepts $(x, w)$ after at most $T$ time steps.
Theorem 1 (restated).
(i) There exists a PCP system \( (P_{\text{RAM}}, V_{\text{RAM}}) \) for \( BH_{\text{RAM}} \) where: for every \((M, x, T) \in BH_{\text{RAM}} \) with a witness \( w \),

- \( P_{\text{RAM}}(M, x, T, w) \) runs in sequential time \((|M|+T)\cdot \text{polylog}(T)\) and parallel time \(O((\log T)^2)\) when given the transcript of \( M \) on \((x, w)\).
- \( V_{\text{RAM}}(M, x, T) \) runs in sequential time \((|M|+|x|)\cdot \text{polylog}(T)\) and parallel time \(O((\log T)^2)\).

(ii) There exists a PCP system for \( s\text{CSAT} \) (cf. Definition 2.2) with a concrete-efficiency threshold (cf. Definition 2.3) that is finite.

Note that, in light of Definition 2.3, it is indeed not clear that a PCP system satisfying the second item exists. For example, if \(|P_{\text{RAM}}(M)| = \Omega(2^n)\), or \(|P_{\text{RAM}}(M)| = \Omega(|F|)\), or \(|Q_{\text{RAM}}(M)| + |D_{\text{RAM}}(M)| = \Omega(|F|^2)\), then \( B = \infty \). Thus the efficiency requirements imposed on a PCP system so to fulfill Definition 2.3 with any finite concrete-efficiency threshold \( B \) (not to mention a small \( B \)) are already quite stringent. Yet, the second item follows from the first via a simple argument, and all the hard work is in proving the first item of the theorem.

2.3 Theorem 2: Concrete Efficiency of Proximity Testing to Reed-Solomon

In this section, we formalize our result (R3) by defining the concrete-efficiency threshold of a PCPP system for a code ensemble (which we informally introduced in Definition 2) and then restating our second main theorem, Theorem 2, more formally.

Recall that an \([n, k, d]_q\)-linear error correcting code (or, simply, \([n, k, d]_q\)-code) is a \( k \)-dimensional subspace \( C \) of \( \mathbb{F}_q^n \), where \( \mathbb{F}_q \) denotes the finite field with \( q \) elements and \( q \) is a prime power, such that every pair \( w \neq w' \) of members of \( C \) differ on at least \( d \) positions. (Later on we shall focus on a special ensemble of codes, namely, Reed-Solomon codes over fields of characteristic 2.) In what follows, let \( (\mathbb{F}_q^n)^{\leq Q} \) denote the set of vectors in \( \mathbb{F}_q^n \) with at most \( Q \) nonzero entries.

Definition 2.5 (PCPP for linear code and LTC). Given \( L, Q \in \mathbb{N} \), an \((L, Q)\)-PCPP system for an \([n, k, d]_q\)-code \( C \) is a pair \((P, V)\) where \( P \) is a linear mapping from \( \mathbb{F}_q^k \) to \( \mathbb{F}_q^L \) and \( V \) is a distribution supported on \((\mathbb{F}_q^n)^{\leq Q}\) satisfying the following conditions:

- Completeness. For every codeword \( w \in C \) and \( \pi := P(w) \) (its associated “proof of proximity”),

\[
\Pr_{v \leftarrow V} \left[ \sum_{i=1}^{n+L} v_i \cdot (w \circ \pi)_i = 0 \right] = 1 ,
\]

where \( w \circ \pi \) is the concatenation of \( w \) and \( \pi \) and arithmetic operations are carried in \( \mathbb{F}_q \).

- Soundness. For every non-codeword \( w \) that is \( d/3 \)-far from \( C \) and every \( \pi \in \mathbb{F}_q^L \),

\[
\Pr_{v \leftarrow V} \left[ \sum_{i=1}^{n+L} v_i \cdot (w \circ \pi)_i = 0 \right] < \frac{1}{2} .
\]

If \( C \) has a \((0, Q)\)-PCPP we say \( C \) is a \( Q \)-query LTC.

Furthermore, for functions \( L \) and \( Q \), an \((L, Q)\)-PCPP system for a (linear) code ensemble \( E \) is a pair \((P, V)\) where, for each \( C \in E \), \((P_C, V_C)\) is an \((L(C), Q(C))\)-PCPP system for \( C \). If \( L(C) = 0 \) for all \( C \in E \), then \( E \) is called an ensemble of LTCs and \( V \) is a tester for \( E \).
Remark 2.6 (possible generalizations). The definition above includes a number of simplifying assumptions and arbitrarily fixed constants. We fix the soundness to be $1/2$ for a proximity parameter that is one-third of the minimal distance of the code. The definition is stated only for linear codes. The mapping sending a message to the PCPP for its codeword is assumed to be linear. The verifier is defined to be non-adaptive, its decision predicate is linear, and it has perfect completeness. Although the latter set of assumptions holds without loss of generality for linear LTCs (cf. [BSHR05, Theorem 3.3]), this is not known to hold for general PCPPs, even assuming the code is linear. Since all these assumptions apply to the codes that we study, we prefer a concrete and simple definition to one that holds in greatest generality (which can anyways be easily deduced from Definition 2.5).

We now provide a definition for a concrete-efficiency threshold for PCPPs for linear code ensembles; this definition is “information-theoretic”, i.e., it does not impose constraints on the computational resources required by the prover and verifier. This is in stark contrast to Definition 2.3 and we discuss the rationale behind this difference below.

Definition 2.7 (concrete-efficiency threshold for PCPPs). Let $\mathcal{E}$ be a linear-code ensemble and $(P,V)$ a PCPP system for $\mathcal{E}$ (cf. Definition 2.5). The concrete-efficiency threshold of $(P,V)$ is the smallest integer $\hat{B}$ such that for every linear code $C \in \mathcal{E}$ that is an $[n,k,d]_q$-code with $k \geq \hat{B}$ it holds that

$$\left(\frac{n + L(C)}{k}\right) \cdot Q(C) < \frac{1}{2} \cdot k.$$  

(3)

If no such integer exists, the concrete-efficiency threshold of $(P,V)$ is infinite (i.e., $\hat{B} := \infty$).

Remark 2.8 (computational vs. information-theoretic concrete efficiency). The cost in Definition 2.3 takes into consideration the computational complexity of the prover and verifier, whereas the cost in Definition 2.7 above only takes into account proof length and query complexity (disregarding the computational complexity required to produce the proof, to sample a query tuple, and then to verify the query answers).

We transition to an information-theoretic definition for codes so to be able to compute the concrete-efficiency threshold for an important family of codes (cf. Theorem 2). Computing a similar concrete-efficiency threshold by taking computational complexity into account (à la Definition 2.3) would require pinning down concrete upper bounds to the circuit-sizes for finite-field arithmetic and interpolation of polynomials (among other things) — a quite difficult analysis. Nonetheless, studying the information-theoretic definition is still meaningful (cf. Remark 2.10).

Case of interest: additive Reed-Solomon. The quasilinear-size PCPs of [BSS08] are based on PCPPs for the ensemble of Reed-Solomon codes over additive subgroups of finite fields of characteristic 2. We define these codes next, for the more convenient case of domains that are shifts of such additive subgroups. Recall that a degree-$\ell$ extension of the two-element field $\mathbb{F}_2$ is also an $\ell$-dimensional linear space over $\mathbb{F}_2$.

Definition 2.9 (additive Reed-Solomon codes over finite fields of characteristic 2). Given a finite field $\mathbb{F}_q$, subset $S$ of $\mathbb{F}_q$, and degree bound $d$, the Reed-Solomon code $\text{RS}(\mathbb{F}_q, S, d)$ is the $[[|S|, d+1, |S|-(d+1)]_q]$-code whose codewords are functions $f : S \rightarrow \mathbb{F}_q$ computed by polynomials of degree at most $d$. The ensemble of Reed-Solomon codes over additive subgroups of fields of characteristic 2, denoted $\mathcal{E}_{RS}$, is defined to be the ensemble of RS-codes $\text{RS}(\mathbb{F}_q, S, d)$ where $q$ is a power of 2 (i.e., $\text{char} (\mathbb{F}_q) = 2$), $S$ is an $\mathbb{F}_2$-affine-subspace, and $d = |S|/8$. 

12
We can now formally restate Theorem 2, our second main theorem:

**Theorem 2** (restated). There exists a PCPP system (cf. Definition 2.5) for the code ensemble $E_{RS}$ (cf. Definition 2.9) having a concrete-efficiency threshold $\hat{B}_{RS} \leq 2^{35}$ (cf. Definition 2.7).

Our strategy for proving Theorem 2 is in two steps: (a) revisit and tighten the Polishchuk–Spielman Bivariate Testing Theorem [PS94] and its corollary that is relevant to us [BSS08, Lemma 6.12]; and (b) provide a class of constructions that generalize the proximity testers of [BSS08] and provide for this class a much tighter and explicit soundness analysis that allows us to numerically evaluate the soundness of the verifier for any given problem size and construction from the class, so that we can then choose a construction with the best $\hat{B}_{RS}$. The proof of Theorem 2, along with a longer discussion of the proof strategy, is given in Section 8.

**Remark 2.10.** Studying $\hat{B}_{RS}$ (cf. Definition 2.7) instead of $B$ (cf. Definition 2.3) is justified because:

- The reductions of Ben-Sasson et al. [BSCGT12] are quasilinear (only $O(\log^3 T)$), and thus it suffices to concentrate on studying the concrete efficiency of the algebraic PCP construction.
- A low-degree test is not only the technical heart of an algebraic PCP, but also its efficiency bottleneck. Indeed, while an algebraic PCP necessarily involves other components (such as verifying vanishing properties of functions), these other components are usually “thin layers” on top of a low-degree test; as a rule of thumb, the low-degree test determines most of the concrete efficiency of an algebraic PCP. And this is certainly the case for our algebraic PCP construction (which is given in Section 7). Thus, it suffices to concentrate on the concrete efficiency of proximity testing to, in our case, certain Reed-Solomon codes.
- While $\hat{B}_{RS}$ does not take into account the running time of the prover, but only its output length, this turns out not to be a problem for the case of Reed-Solomon codes, because the PCPP systems we use only require basic arithmetic in the ring of multivariate polynomials over finite fields of characteristic 2. Indeed, through the use of appropriate additive-FFT techniques [Mat08] and invoking various properties of linearized polynomials [LN97, Section 2.5], we show that the running time of the prover closely follows its output size and the running time of the verifier closely follows its query complexity.

We thus expect the “real” $B$ to not be far from $\hat{B}_{RS}$. For algorithmic details, see Appendix B.

### 2.4 Theorem 3: Properties for Cryptographic Constructions

In this section, we discuss result (R4) in more detail.

Our Theorem 3 states that the PCPs we construct in the proof of Theorem 1 satisfy properties that are needed in several cryptographic constructions. Specifically, we prove that the PCPs we construct satisfy the following three properties:

(A) **“Explicit” PCP proof of knowledge.** We show that whenever the PCP verifier is convinced with sufficiently large probability, the PCP proof can be decoded to a valid witness by running a knowledge extractor that runs in time proportional to the size of the witness.

---

6In fact, we note that it is a non-trivial concern how to make even the verifier run efficiently at all (not to mention in time that is close to the query complexity). Working with univariate low-degree polynomials means that the verifier will have to test proximity for degrees that are enormous; therefore, any “reasoning about high-degree polynomials” must be conducted in a succinct way. The sparsity of linearized polynomials, induced by the use of subspaces as domains of evaluation for the Reed-Solomon code, will enable the verifier to do so.
Note that we cannot expect the existence of a knowledge extractor that is able to locally decode bits of the witness by having oracle access to a PCP proof. The lack of local decoding here is inherent because our PCPs, as those of [BSS08, BSGH+05], rely on “univariate techniques” (cf. Remark 11.39). Thus, because we do not achieve a knowledge extractor that is an implicit representation of the valid witness, we call the knowledge property we achieve explicit PCP proof of knowledge.

(B) Non-adaptivity of the PCP verifier. We show that the PCP verifier can be split into a query algorithm and a decision algorithm. It is rather obvious from our PCP construction that this is the case, but working out these algorithms for the more complex components of the construction is quite non-trivial. We explicitly carry out this separation and provide an algorithmic specification for the query and decision algorithms of our PCP verifier (in addition to the algorithmic specification of the “non-split” verifier already contained Appendix B). This provides a reference for others wishing to study the concrete efficiency of cryptographic constructions where the query and decision algorithms are invoked.

(C) Efficient reverse-samplability of the PCP verifier. We show that there is an efficient algorithm that, given a query number and an index into the PCP oracle, is able to output a string that is uniformly distributed among those that could indeed have produced the index when given as input the query number — this algorithm is thus an efficient reverse sampler. That our PCP construction is reverse samplable is not obvious; we show that it is by constructing an efficient reverse sampler for it.7

Using our PCPs in cryptographic constructions. The explicit PCP proof of knowledge mentioned above falls short of the one needed in the construction of universal arguments [BG08], where a knowledge extractor that is able to perform local decoding of the witness is needed. Nonetheless, we show that the same construction as [BG08, Construction 3.4] still gives us succinct interactive arguments of knowledge for NP.

More precisely, our result is stronger than just stated: we obtain universal arguments where the knowledge extractor may run in time that is polynomial (rather than polylogarithmic as in [BG08]) in the witness length — we call these almost universal arguments. (In particular, for example, with a mild superpolynomial-hardness assumption, we can obtain universal arguments for NP.) Once again, this limitation is only natural in light of the fact that our PCPs can only satisfy an “explicit” proof-of-knowledge property, with no local decoding of the witness.

Nonetheless, the aforementioned limitation is actually not a problem because succinct arguments of knowledge for NP suffice for most “positive” applications of PCPs, where the relevant computations to be verified anyways “lie in NP” (cf. Remark 11.2).

The properties that we use in the construction of almost universal arguments, following [BG08, Construction 3.4], are a superset of the properties required of PCPs in other cryptographic applications such as [Mic00, Val08, CT10, BCCT11, CT12]. Thus, in the proof, it will suffice to focus on the construction of almost universal arguments.

The proof of Theorem 3 is given in Section 11.

3 Open Questions

We list here several intriguing questions that our work leaves unanswered.

7This fact was already by Mie [Mie09] for a special case of the proximity testers underlying our PCPs; he used their efficient reverse samplability for showing a verifier-efficient construction of gap amplification [Din07].
Complexity-preserving PCPs. Our Theorem 1 guarantees the existence of a PCP system in which the prover and verifier respectively run in time $(|P| + T) \cdot \text{polylog}(T)$ and $(|P| + |x|) \cdot \text{polylog}(T)$, when proving and verifying that a program $P$ accepts $(x, w)$ for some $w$. These running times are essentially optimal. However, the running time of the prover is achieved via the use of FFT-like methods, which means that its space complexity is $\Omega(T)$ regardless of the space complexity of $P$. Let us define a PCP system to be complexity preserving if it has the aforementioned running times and, in addition, the prover runs in space $(|M| + |x| + S) \cdot \text{polylog}(T)$ when $P$ uses at most space $S$. Do complexity-preserving PCPs exist? Bitansky and Chiesa [BC12] have constructed a complexity-preserving multi-prover interactive proof (MIP) [BOGKW88], but it is unclear whether complexity-preserving PCPs can be constructed or not.

Local decoding of PCPs. Our Theorem 1 states that the PCPs from our Theorem 1 can be used to construct a weaker variant of universal arguments [BG08]. As discussed, the single reason why we do not obtain (full) universal arguments is that our PCPs, being based on techniques that use univariate polynomials, do not enjoy good local decoding properties. Are there universal arguments where the prover and verifier running times are essentially optimal? Bitansky and Chiesa [BC12] use their complexity-preserving MIP construction to obtain complexity-preserving universal arguments with private coins, but the public-coin case (often crucial in applications) remains open (even without posing requirements on the space complexity of the prover).

Limits of concrete efficiency. We have introduced a new efficiency measure for PCPs that attempts to capture how “soon” a PCP becomes useful for the purpose of succinct verification of long computations and have shown progress relative to this complexity measure. How far can the concrete efficiency of PCPs be pushed? We are optimistic that additional work in this direction will discover surprisingly efficient PCP constructions. A natural starting point would be to understand what is the optimal value of the universal constant of bivariate testing (see Section 8.1).
4 Definitions

We present formal definitions for the basic notions that we use throughout this paper.

4.1 Reed-Solomon and Reed-Muller Codes

Definition 4.1. Let $\mathbb{F}$ be a field and $S$ a subset of $\mathbb{F}$. The evaluation of a polynomial $P(x) = \sum_{i=0}^{d} a_i x^i$ over $S$ is the function $p: S \to \mathbb{F}$ defined by $p(s) = P(s)$ for all $s \in S$. The formal sum $P(x)$ is called the polynomial corresponding to (the function) $p$. Similar definitions hold for multivariate polynomials.

Definition 4.2. Let $\mathbb{F}$ be a field and $d \geq 0$. A polynomial $P(x)$ over $\mathbb{F}$ has degree $d$ if the degree of $P$ in $x$ is at most $d$.

Definition 4.3. Let $\mathbb{F}$ be a field, $S$ a subset of $\mathbb{F}$, and $d \geq 0$. The Reed-Solomon code of degree $d$ over $\mathbb{F}$ evaluated at $S$ is the set of functions $RS(\mathbb{F}, S, d) := \{ p: S \to \mathbb{F} \text{ s.t. } p \text{ is an evaluation of a polynomial of degree at most } d \text{ over } S \}$.

Definition 4.4. Let $\mathbb{F}$ be a field, $S$ and $H$ subsets of $\mathbb{F}$, and $d \geq 0$. The $H$-vanishing Reed-Solomon code of degree $d$ over $\mathbb{F}$ evaluated at $S$ is the set of functions $VRS(\mathbb{F}, S, H, d) := \{ p \in RS(\mathbb{F}, S, d) \text{ s.t. the polynomial corresponding to } p \text{ vanishes on } H \}$.

Definition 4.5. Let $\mathbb{F}$ be a field and $d, e \geq 0$. A polynomial $P(x, y)$ over $\mathbb{F}$ has degree $(d, e)$ if the degree of $P$ in $x$ is at most $d$ and the degree of $P$ in $y$ is at most $e$.

Definition 4.6. Let $\mathbb{F}$ be a field, $W$ a subset of $\mathbb{F} \times \mathbb{F}$, and $d, e \geq 0$. The bivariate Reed-Muller code of degree $(d, e)$ over $\mathbb{F}$ evaluated at $W$ is the set of functions $RM(\mathbb{F}, W, (d, e)) := \{ p: W \to \mathbb{F} \text{ s.t. } p \text{ is an evaluation of a bivariate polynomial of degree at most } (d, e) \text{ over } W \}$.

4.2 Notions of Distance

Next, we recall the notions of fractional (or relative) distance between strings and to low-degree polynomials. (In general, when we say “close” we shall mean “≤” and when we say “far” we shall mean “>”.)

The fractional (or relative) Hamming distance between two strings is the ratio between the number of positions where the two strings differ divided by their length:

Definition 4.7. Let $\Sigma$ be a finite alphabet and $N$ a positive integer. For any two $\Sigma$-strings $a$ and $b$ in $\Sigma^N$, the fractional (Hamming) distance over the alphabet $\Sigma$ between $a$ and $b$, denoted $\Delta_N(a, b)$, is equal to the number of positions where $a$ and $b$ differ divided by their length:

$$\Delta_N(a, b) := \frac{|\{i \in N : a_i \neq b_i\}|}{N}.$$ 

The definition easily extends to functions from $N$ to $\Sigma$, as it is possible to think of the $\Sigma$-strings $a$ and $b$ as functions $\tilde{a}, \tilde{b}: N \to \Sigma$ where $\tilde{a}(i) = a_i$ and $\tilde{b} = b_i$ for each $i \in N$. 

16
The fractional Hamming distance between two functions allows to define the fractional Hamming distance of a function to low-degree polynomials:

**Definition 4.8.** Let $\mathbb{F}$ be a field, $V$ a subset of $\mathbb{F}$, $f: V \rightarrow \mathbb{F}$ a univariate function, and $d \geq 0$. We denote by $\delta_v^{(d)}(f)$ the fractional Hamming distance of $f$ to $\text{RS}(\mathbb{F}, V, d)$, i.e.,

$$\delta_v^{(d)}(f) := \inf_{P \in \mathbb{F}[x]} \Delta_v(f, P).$$

**Definition 4.9.** Let $\mathbb{F}$ be a field, $W$ a subset of $\mathbb{F} \times \mathbb{F}$, $f: W \rightarrow \mathbb{F}$ a bivariate function, and $d, e \geq 0$. We denote by $\delta_w^{(d,e)}(f)$ the fractional Hamming distance of $f$ to $\text{RM}(\mathbb{F}, W, (d,e))$, i.e.,

$$\delta_w^{(d,e)}(f) = \inf_{Q \in \mathbb{F}[x,y]} \Delta_w(f, Q).$$

Furthermore, we denote by $\delta_w^{(d,\ast)}(f)$ the fractional distance when the degree in $y$ is unrestricted, and by $\delta_w^{(\ast,e)}(f)$ the fractional distance when the degree in $x$ is unrestricted.

Univariate low-degree polynomials form a code with a certain distance:

**Lemma 4.10.** Fix a field $\mathbb{F}$, a subset $S \subseteq \mathbb{F}$, and an integer $d \in \mathbb{N}$. For any two distinct polynomials $P, P': \mathbb{F} \rightarrow \mathbb{F}$ of degree at most $d$, it holds that $\Delta_S(P, P') > 1 - \frac{d}{|S|}$.

In particular, we can deduce the “unique decoding radius” for univariate low-degree polynomials:

**Lemma 4.11.** Fix a field $\mathbb{F}$, a subset $S \subseteq \mathbb{F}$, an integer $d \in \mathbb{N}$, and $\delta \in [0,1]$. If a function $p: S \rightarrow \mathbb{F}$ is $\delta$-close to $\text{RS}(\mathbb{F}, S, d)$ and $1 - \frac{d}{|S|} > 2\delta$ then there is a unique polynomial $P$ of degree at most $d$ whose evaluation over $S$ is $\delta$-close to $p$.

Recall that Reed-Solomon codes have an efficient decoding procedure (e.g., via the Welch–Berlekamp algorithm [WB86, GS92]):

**Claim 4.12 (Decoding Reed-Solomon Codes).** There exists a polynomial-time algorithm $\text{DECODE}_{\text{RS}}$ that, on input (the representation of) a finite field $\mathbb{F}$, a subset $S$ of $\mathbb{F}$, a degree $d$ (presented in unary), and a function $p: S \rightarrow \mathbb{F}$, outputs a polynomial $P: \mathbb{F} \rightarrow \mathbb{F}$ of degree at most $d$ whose evaluation over $S$ is closest to $p$, provided that $p$ lies in the unique decoding radius.

### 4.3 PCPs and PCPPs

We formally introduce probabilistically-checkable proofs and probabilistically-checkable proofs of proximity, as well as the functions that will help us keep track of their various complexity parameters.

**PCPs.** We first recall the standard definition of a probabilistically-checkable proof (PCP). For functions $r, q: \mathbb{N} \rightarrow \mathbb{N}$ we say that a probabilistic oracle machine $V$ is a $(r,q)$-PCP verifier if, on input a binary string $x$ of length $n$ and given oracle access to a binary string $\pi$, $V$ runs in time $2^{O(r(n))}$, tosses $r(n)$ coins, makes $q(n)$ queries to $\pi$, and outputs either 1 (“accept”) or 0 (“reject”).
Definition 4.13. Let \( s \in [0, 1] \) and \( r, q : \mathbb{N} \rightarrow \mathbb{N} \). A language \( L \) belongs in the class \( \text{PCP}_{s}[r(n), q(n)] \) if there exists a \((r, q)\)-PCP verifier \( V_L \) such that the following holds:

1. **(Perfect) Completeness:** If \( x \in L \) then there exists \( \pi \) such that \( \Pr_{R}[V^{(y,\pi)}_L(x; R) = 1] = 1 \).

2. **Soundness:** If \( x \not\in L \) then for every \( \pi \) it holds that \( \Pr_{R}[V^{(y,\pi)}_L(x; R) = 1] \leq s \).

PCPs of Proximity. A PCP of Proximity (PCPP) \([\text{BSGH}^+06]\) is a strengthening of a PCP where the input comes in two parts \((x, y)\), where \( x \), the **explicit input**, is given explicitly to the verifier and \( y \), the **implicit input**, is only given as an oracle to the verifier (and queries to it are counted as part of the query complexity); the explicit input is of the form \( x = (x', N) \) and \( N \) is the length of \( y \). Because now the verifier may not see the input in its entirety, it only makes sense to require verifiers to test theorems for being “close” to true theorems.

More precisely, one considers **pair languages** (which are simply binary relations). For a pair language \( L \) and a binary string \( x \), we define \( L_x \) to be all the \( N \)-bit strings \( y \) such that \((x, y) \in L\). Then, for an arbitrary \( y \), we define \( \Delta(y, L_x) \) to be 1 if \( L_x = \emptyset \) else to be the smallest fractional Hamming distance of \( y \) to any element in \( L_x \).

For functions \( r, q : \mathbb{N} \rightarrow \mathbb{N} \) we say that a probabilistic oracle machine \( V \) is a \((r, q)\)-PCPP verifier if, given an explicit input \( x = (x', N) \) with \( |x'| = n \) and oracle access to an \( N \)-bit implicit input \( y \) and proof \( \pi \), \( V \) runs in time \( 2^{O(r(n))} \), tosses \( r(n) \) coins, makes \( q(n) \) queries to \((y, \pi)\), and outputs either 1 ("accept") or 0 ("reject").

Definition 4.14. Let \( s, \delta \in [0, 1] \) and \( r, q : \mathbb{N} \rightarrow \mathbb{N} \). A **pair language** \( L \) belongs to the class \( \text{PCP}_{s,\delta}[r(n), q(n)] \) if there exists a \((r, q)\)-PCPP verifier \( V_L \) such that the following holds:

1. **(Perfect) Completeness:** If \((x, y) \in L \) then there exists \( \pi \) such that \( \Pr_{R}[V^{(y,\pi)}_L(x; R) = 1] = 1 \).

2. **Soundness:** If \( \Delta(y, L_x) \geq \delta \) then for every \( \pi \) it holds that \( \Pr_{R}[V^{(y,\pi)}_L(x; R) = 1] \leq 1 - s \).

We call \( \delta \) the **proximity parameter**.

We also consider a stronger notion of PCPPs, where the probability of rejection is proportional to the distance of \( y \) from \( L_x \).

Definition 4.15. Let \( s \in (0, 1] \times \mathbb{N} \rightarrow (0, 1] \) and \( r, q : \mathbb{N} \rightarrow \mathbb{N} \). A **pair language** \( L \) belongs to the class \( \text{Strong-PCP}_{s(\delta, n)}[r(n), q(n)] \) if there exists a \((r, q)\)-PCPP verifier \( V_L \) such that the following holds:

1. **(Perfect) Completeness:** If \((x, y) \in L \) then there exists \( \pi \) such that \( \Pr_{R}[V^{(y,\pi)}_L(x; R) = 1] = 1 \).

2. **Soundness:** For every \( \pi \) it holds that \( \Pr_{R}[V^{(y,\pi)}_L(x; R) = 1] \leq 1 - s(\Delta(y, L_x), n) \).

**Complexity parameters** Throughout we will denote by \( \text{rand}(\cdot) \) the randomness complexity, by \( \text{query}(\cdot) \) the query complexity, and by \( \text{length}(\cdot) \) the proof length of the various PCPs and PCPPs that we will consider.\(^8\) (The arguments to these functions will change from verifier to verifier, but will be given explicitly each time, and will be clear what they are.)

\(^8\)More precisely, for PCPs of Proximity, the length will not account for the length of the object being tested.
5 Proof of Theorem 1

In this section we prove Theorem 1, discussed in Section 1.3 and formally stated in Section 2.2.

High-level strategy. It is useful to break the problem of constructing PCPs for BH\textsubscript{RAM} with stringent efficiency requirements into two different subproblems: (a) constructing a very efficient PCP system for some “PCP-friendly” NEXP-complete problem \( \mathcal{P} \), and (b) constructing tight reductions from BH\textsubscript{RAM} to \( \mathcal{P} \). Indeed, PCPs are only known to exist for certain problems having strong algebraic or combinatorial structure. Typically, one also defines a flexible interface between the two aforementioned subproblems (a) and (b), in order to create some “modularity”. Following and generalizing [BSGH+05], we thus introduce a family of succinct algebraic constraint satisfaction problems (sACSP) attempting to simultaneously capture the essential ingredients that make a problem amenable to (“direct”) probabilistic checking as well as be general enough to make it easy to reduce from less structured (natural) problems (such as BH\textsubscript{RAM}).

In other words, we choose \( \mathcal{P} := \text{sACSP} \). This choice “decouples” (a) and (b), and progress can be made independently on each subproblem. In light of the aforementioned decoupling, our proof of the first item of Theorem 1 relies on two ingredients: (a) an algebraic PCP construction for sACSP, and (b) the use of reductions of Ben-Sasson et al. [BSCGT12] from BH\textsubscript{RAM} to sACSP.

As for the second item of Theorem 1 (claiming a PCP system for sCSAT with \( B < \infty \)), we show that it follows from the first item.

The family of succinct algebraic constraint satisfaction problems sACSP is introduced and defined in Section 6. Following is the proof of Theorem 1.

Proof of Theorem 1. Let us begin with proving the first item. For a random-access machine \( M \), let \( |M| \) denote the size of the transition function of \( M \) when viewed as a Boolean circuit and \( \deg(M) \) the total degree of this circuit when viewed as a polynomial. We begin by establishing the following claim:

Claim 5.1. There is a PCP system \((P'_{\text{RAM}}, V'_{\text{RAM}})\) where, in order to verify that a random-access machine \( M \) accepts \((x, w)\), for some \( w \), within \( T \) steps (with \( |x|, |w| \leq T \)),

- the prover runs in sequential time \(|M| \cdot T \cdot \text{polylog}(T) \cdot \deg(M)\) and parallel time \(O((\log T + \log \deg(M))^2)\) when given a transcript of computation of \( M \) on \((x, w)\), and
- the verifier in sequential time \((|M| + |x|) \cdot \text{polylog}(T + \deg(M))\) and parallel time \(O((\log T + \log \deg(M))^2)\).

Proof. Ben-Sasson et al. [BSCGT12] study reductions from bounded-halting problems on random-access machines, denoted BH\textsubscript{RAM}, to sACSP. Specifically, for a given random-access machine \( M \), BH\textsubscript{RAM}(\( M \)) is the language of pairs \((x, T)\) such that the random-access machine \( M \) non-deterministically accepts \( x \) within \( T \) steps (with \( |x| \leq T \)). It is convenient to assume without loss of generality that all instances \((x, T)\) have \( T \) that is a positive power of 2, so that we can represent an instance \((x, 2^t)\) via the string \((x, 1^t)\).

We shall thus focus on algebraic PCPs. The reason is that present PCP technology suggests greater flexibility and understanding of computational aspects of such PCPs; e.g., we know of quasilinear-size PCPs only via algebraic techniques [BSS08], and have a good picture of computational aspects of algebra [vzGG03]. (Also see Remark 7.10.)

We think that such a decoupling is a significant simplification of the problem of constructing practical PCPs in general, given the amount of work that goes towards satisfying solutions of either subproblem and given that the two subproblems are different in flavor and thus demand for quite different sets of techniques.
A reduction from $\text{BH}_{\text{RAM}}$ to $\text{sACSP}$ is a pair $(\Phi, \Psi)$ of efficient transformations such that:

- For every random-access machine $M$,
  \[
  \text{par}^M := \Phi(M) = \left( f, (m_H, t_H, H), (c_N, t_N, s_N, N), (t_p, s_p, P), (t_1, I) \right)
  \]
is a choice of parameters for $\text{sACSP}$; in other words, $\text{par}^M$ specifies, for each positive integer $t$, what algebraic constraints are to be used to verify membership of instances of the form $(x, 1^t)$. (See Definition 6.1 in Section 6 for the formal definition of $\text{sACSP}$.)

- For every random-access machine $M$ and instance $(x, 1^t)$, it holds that $(x, 1^t) \in \text{BH}_{\text{RAM}}(M)$ if and only if $(x, 1^t) \in \text{sACSP}(\text{par}^M)$.

- For every random-access machine $M$ and instance $(x, 1^t)$, if $w$ is a witness to the fact that $(x, 1^t) \in \text{BH}_{\text{RAM}}(M)$, then $A := \Psi(M, w)$ is a witness to the fact that $(x, 1^t) \in \text{sACSP}(\text{par}^M)$.

At high level, the construction of the PCP system $(P'_{\text{RAM}}, V'_{\text{RAM}})$ consists of first invoking the reductions of Ben-Sasson et al. [BSCGT12] from $\text{BH}_{\text{RAM}}$ to $\text{sACSP}$ and then invoking the PCP system $(P_{\text{ACSP}}, V_{\text{ACSP}})$ for $\text{sACSP}$ guaranteed by our Theorem 7.1 from Section 7.\footnote{Ultimately, when proving Theorem 3, we will in fact need Levin reductions, where we are additionally guaranteed the existence of an “inverse” to the witness reduction $\Psi$, so to ensure that the knowledge property of our PCP system $(P_{\text{ACSP}}, V_{\text{ACSP}})$ is preserved by the reductions. The reductions of Ben-Sasson et al. [BSCGT12] are Levin reductions, so this is not a problem; see the proof of Theorem 3 and Remark 11.1 in Section 11.}

More precisely, the PCP prover $P'_{\text{RAM}}$ and the PCP verifier $V'_{\text{RAM}}$ work as follows.

- $P'_{\text{RAM}}$, on input a random-access machine $M$, instance $(x, 1^t)$, and witness $w$ such that $M(x, w)$ accepts within $2^t$, performs the following steps:
  1. compute $\text{par}^M := \Phi(M)$;
  2. compute $A := \Psi(M, w)$;
  3. compute $\pi := P_{\text{ACSP}}((x, 1^t), A)$, with choice of parameters $\text{par}^M$;
  4. output $\pi$.

- $V'_{\text{RAM}}$, on input a random-access machine $M$ and instance $(x, 1^t)$, and with oracle access to a PCP oracle $\pi$, performs the following steps:
  1. compute $\text{par}^M := \Phi(M)$;
  2. compute $b := V'_{\text{ACSP}}((x, 1^t))$, with choice of parameters $\text{par}^M$;
  3. output $b$.

Due to the soundness guarantees of the reduction $\Phi$, $(P'_{\text{RAM}}, V'_{\text{RAM}})$ is a PCP system for bounded-halting problems on random-access machines. We are thus only left to argue its efficiency.

The reductions of Ben-Sasson et al. [BSCGT12] generate choices of parameters $\text{par}^M$ that are “natural”, so that Theorem 7.1 ensures that $P_{\text{ACSP}}$ runs in time $s_p(1^t) \cdot 2^t \cdot \text{poly}(f(t))$ and $V_{\text{ACSP}}$ runs in time $\left(|x| + s_p(1^t)\right) \cdot \text{poly}(f(t))$. (See Remark 7.2.) Furthermore, in Ben-Sasson et al. [BSCGT12], it holds that $s_p(1^t) = |M| \cdot \text{poly}(f(t))$ and $2^t = 2^t \cdot \text{polylog}(2^t) \cdot \text{deg}(M)$. Putting these two facts together yields the desired sequential efficiency for $(P'_{\text{RAM}}, V'_{\text{RAM}})$. The parallel efficiency can be similarly argued.

\footnote{Ultimately, when proving Theorem 3, we will in fact need Levin reductions, where we are additionally guaranteed the existence of an “inverse” to the witness reduction $\Psi$, so to ensure that the knowledge property of our PCP system $(P_{\text{ACSP}}, V_{\text{ACSP}})$ is preserved by the reductions. The reductions of Ben-Sasson et al. [BSCGT12] are Levin reductions, so this is not a problem; see the proof of Theorem 3 and Remark 11.1 in Section 11.}
We now return to the proof of Theorem 1. To deduce the first item, we can fix a universal random-access machine $U$ where both $|U|$ and $\deg(U)$ are on the order of $\text{polylog}(T)$, and then simulate a given random-access machine $M$ (computing on a given $(x, w)$) on $U$ step by step. The overhead at each step is polynomial in the register sizes, which is only $O(\log T)$. Thus, overall, simulating $M$ on $U$ is only $\text{polylog}(T)$ slower than running $M$ directly. Combining this with Claim 5.1 yields a PCP system $(P_{\text{RAM}}, V_{\text{RAM}})$ satisfying the first item of the theorem.

As for the second item, it suffices to construct a PCP system for $\text{sCSAT}$ where the prover runs in time $|F| \cdot 2^n \cdot \text{poly}(n)$ and the verifier runs in time $|F| \cdot \text{poly}(n)$. So let $M^*$ be the random-access machine that, on input a circuit description $F$, will non-deterministically verify that $F \in \text{sCSAT}$; note that this can be done in time $T := O(|F| \cdot 2^n)$ when $F$ describes a circuit of size $2^n$. We can now use the PCP system $(P_{\text{RAM}}, V_{\text{RAM}})$ on the random-access machine $M^*$. Doing so yields a PCP system for $\text{sCSAT}$ where the prover runs in time $|F| \cdot 2^n \cdot \text{poly}(n)$ and the verifier runs in time $|F| \cdot \text{poly}(n)$, as desired.

In the proof of the second item of Theorem 1 we relied on fast reductions from random-access machines. We note that attempting to prove the second item of Theorem 1 via a “direct” reduction from $\text{sCSAT}$ to $\text{sACSP}$ through a naive use of the techniques contained in [BSCGT12] will not work. Indeed, if we were to simply route the circuit represented by $F$ using De Bruijn graphs (in a similar manner as in [PS94], by also paying attention to the succinctness of the reduction) and then arithmetize the resulting coloring problem, it will not work; the reason is that the degree of $F$ when viewed as a polynomial may be too high and cause the reduction to be too expensive (e.g., quadratic). The “right” way to do this without relying on random-access machines would be to route a universal circuit that performs a computation similar to the random-access machine $M^*$ that we chose; by ensuring that the universal circuit has a highly-structured topology, the description of the universal circuit would be shallow, and thus this description, when viewed as a polynomial, would have low enough degree for the reduction to work out. But this direct reduction would be unnecessarily complicated, and taking a path, as we do, through random-access machines is more natural and cleaner.
6 A Succinct Algebraic Constraint Satisfaction Problem

sACSP is a class of succinct algebraic constraint satisfaction problems, each specified by a list of parameters, for univariate polynomials over finite field extensions of GF(2). Roughly, sACSP is simply a class of succinct graph-coloring problems that must respect certain algebraic constraints.

Each particular sACSP problem simultaneously allows for the construction of PCPs with quasilinear-time prover and succinct verifier (as we will show in Section 7) and is flexible enough to support (several) fast reductions from high-level languages such as computations on random-access machines, as shown by Ben-Sasson et al. [BSCGT12].

Informally, a choice $\text{par}$ of parameters of sACSP consists of the following:

- A field size function $f: \mathbb{N} \to \mathbb{N}$, inducing a finite field family $\{F_T\}_{T \in \mathbb{N}} := \{GF(2^{f(T)})\}_{T \in \mathbb{N}}$.
- A family $\{H_T\}_{T \in \mathbb{N}}$, where each $H_T$ is an affine subspace of $F_T$.
- A family $\{\vec{N}_T\}_{T \in \mathbb{N}}$, where each $\vec{N}_T$ is a vector of neighbor polynomials.
- A family $\{P_T\}_{T \in \mathbb{N}}$, where each $P_T$ is a constraint polynomial.
- A family $\{\vec{I}_T\}_{T \in \mathbb{N}}$, where each $\vec{I}_T$ is a vector of affine subspaces each contained in $H_T$.

A certain algebraic relation constrains which parameters are possible. A reduction to sACSP will concretely instantiate a choice of the above parameters.

A pair $(x, T)$ is a member of the language $sACSP(\text{par})$ if it fulfills the following: there exists a low-degree assignment polynomial $A: F_T \to F_T$ that "colors" elements of the field $F_T$ such that (1) for every element $\alpha$ of the subspace $H_T$, the constraint polynomial $P_T$, when given as input the colors in the "$\vec{N}_T$-induced neighborhood" of $\alpha$, is satisfied; and (2) the colors of elements in the $(\log |x|)$-th affine subspace in $\vec{I}_T$ are consistent with $x$.

Crucially, for each of the families in $\text{par}$, the $T$-th object must be able to be "understood" in time $\text{polylog}(T)$ (e.g., generating an element in $H_T$, generating an arithmetic circuit for each polynomial in $\vec{N}_T$, etc.); this is the requirement of succinctness of the problem. Additional properties that are essential for us to construct PCPs with a quasilinear-time prover and succinct verifier include, for example, the fact that $H_T$ is an affine subspace (so that one may leverage the computational properties of linearized polynomials [LN97, Section 2.5]).

In the formal discussions, it will in fact be more convenient to index the above families by $t$, where the $t$-th elements will correspond to problems of size $T \approx 2^t$.

Formally:

**Definition 6.1** (Succinct Algebraic Constraint Satisfaction). Consider the following parameters:

1. a field size function $f: \mathbb{N} \to \mathbb{N}$, inducing a family of finite fields $\{F_t\}_{t \in \mathbb{N}}$ where $F_t = \mathbb{F}_2(x)$ and $x$ is the root of $I_t$, which is the irreducible polynomial of degree $f(t)$ over $\mathbb{F}_2$ output by $\text{FindIrrPoly}(1/f(t))$;

2. two proper functions associated with the family $\mathbf{H}$ in Parameter 3:
   (a) a dimension function $m_H: \mathbb{N} \to \mathbb{N}$, and
   (b) a time function $t_H: \mathbb{N} \to \mathbb{N}$.
The language \text{sACSP} algebraic constraint must hold:

\begin{equation}
\forall t \in \mathbb{N}, \quad \deg \left( P_t \left( x, x^{(2^nH(t)-1)\deg(N_{t,1})}, \ldots, x^{(2^nH(t)-1)\deg(N_{t,mN(t)})} \right) \right) \leq 2^{l(t)-2}.
\end{equation}

The language \text{sACSP}, with respect to a choice \( \text{par}_{\text{sACSP}} \)

\[ \text{par}_{\text{sACSP}} = \left( f, (m_t, t_H, H), (c_N, t_N, s_N, N), (t_P, s_P, P), (t_t, I) \right) \]

of the above parameters, consists of instances \((x, 1^t)\), where \(x\) is a binary input string and \(t \in \mathbb{N}\) with \(|x| \in \{2, \ldots, 2^t\}\), such that there exists an assignment polynomial \(A : \mathbb{F}_t \to \mathbb{F}_t\) of degree less than \(2^nH(t)\) for which the following two conditions hold:

3. a family \(H = \{H_t\}_{t \in \mathbb{N}}\) such that:
   (a) \(H_t\) is an \(\mathbb{m}_H(t)\)-dimensional affine subspace of \(\mathbb{F}_t\) specified by a basis \(B_{H_t}\) and an offset \(O_{H_t}\) for all \(t \in \mathbb{N}\), and
   (b) there exists a \(t_H\)-time algorithm \text{FIND}H such that \((B_{H_t}, O_{H_t}) = \text{FIND}H(1^t)\) for all \(t \in \mathbb{N}\);

4. three proper functions associated with the family \(N\) in Parameter 5:
   (a) a neighborhood size function \(c_N : \mathbb{N} \to \mathbb{N}\),
   (b) a time function \(t_N : \mathbb{N} \to \mathbb{N}\), and
   (c) a size function \(s_N : \mathbb{N} \to \mathbb{N}\);

5. a family \(N = \{N_t\}_{t \in \mathbb{N}}\) such that:
   (a) \(\vec{N}_t = (N_{t,i} : \mathbb{F}_t \to \mathbb{F}_t)_{i=1}^{c_N(t)}\) is a vector of \(c_N(t)\) neighbor polynomials over \(\mathbb{F}_t\), and
   (b) there exists a \(t_N\)-time algorithm \text{FIND}N such that \([N_{t,j}]^A = \text{FIND}N(1^t, i)\) is an \(s_N\)-size \(\mathbb{F}_t\)-arithmetic circuit computing \(N_{t,i}\) for all \(t \in \mathbb{N}\) and \(i \in \{1, \ldots, c_N(t)\}\);

6. two proper functions associated with the family \(P\) in Parameter 7:
   (a) a time function \(t_P : \mathbb{N} \to \mathbb{N}\), and
   (b) a size function \(s_P : \mathbb{N} \to \mathbb{N}\);

7. a family \(P = \{P_t\}_{t \in \mathbb{N}}\) such that:
   (a) \(P_t : \mathbb{F}_t^{1+c_N(t)} \to \mathbb{F}_t\) is a constraint polynomial, and
   (b) there exists a \(t_P\)-time algorithm \text{FIND}P such that \([P_t]^A = \text{FIND}P(1^t)\) is a \(s_P\)-size \(\mathbb{F}_t\)-arithmetic circuit computing \(P_t\) for all \(t \in \mathbb{N}\);

8. a proper function associated with the family \(I\) in Parameter 9:
   (a) a time function \(t_I : \mathbb{N} \to \mathbb{N}\);

9. a family \(I = \{I_t\}_{t \in \mathbb{N}}\) such that:
   (a) \(\vec{I}_t = (I_{t,m})_{m=1}^{m=1}\) is a vector of affine subspaces each contained in \(H_t\) specified by a basis \(B_{H_t,m}\) of \(m\) elements and an offset \(O_{H_t,m}\) for all \(t \in \mathbb{N}\), and
   (b) there exists a \(t_I\)-time algorithm \text{FIND}I such that \((B_{H_t,m}, O_{H_t,m}) = \text{FIND}I(1^t, 1^m)\) for all \(t \in \mathbb{N}\) and \(m \in \{1, \ldots, t\}\).
(i) Satisfiability of constraints. For every element $\alpha \in H_t$, 

$$P_t\left(\alpha, (A \circ N_{t,1})(\alpha), \ldots, (A \circ N_{t,cN(t)})(\alpha)\right) = 0_{F_t}.$$ 

If so, we say that the assignment polynomial $A$ satisfies the constraint polynomial $P_t$.

(ii) Consistency with the input. Letting $\alpha_i$ be the $i$-th element in $I_{t,\log|\pi|}$ for every index $i \in \{1, \ldots, |\pi|\}$, 

$$x = \text{bit}(A(\alpha_1)) \cdots \text{bit}(A(\alpha_{|\pi|})),$$

where $\text{bit}: F_t \to \{0, 1, \bot\}$ maps $0_{F_t}$ to 0, $1_{F_t}$ to 1, and anything else to $\bot$. If so, we say that the assignment polynomial $A$ is consistent with the input $x$.

Remark 6.2. Definition 6.1 follows related definitions that have appeared in [BSS08] and [BSGH+05]. We briefly discuss here how our definition compares to the previous ones.

The definition of Ben-Sasson and Sudan [BSS08, Definition 3.6] considers low-degree polynomials vanishing at every affine neighborhood of a certain subset of a finite field; however, their definition (as is clear from its compactness!) does not require succinctness (for example, the subset $H$ need not be an affine subspace) because their paper does not attempt to construct PCP verifiers that are succinct in time. (Also note that, in the non-succinct case, the “consistency with the instance” requirement disappears.)

The later paper of Ben-Sasson et al. [BSGH+05], which constructs efficient PCP verifiers, does indeed give a definition [BSGH+05, Definition 6.1] for a succinct problem about polynomials (similar to the previous one of Ben-Sasson and Sudan [BSS08, Definition 3.6]), but is specific for the parameters obtained when reducing from bounded halting problems on Turing machines.

Definition 6.1 is thus a generalization of [BSGH+05, Definition 6.1] that leaves unspecified degrees of freedom that we believe important for “supporting” a variety of reductions from other models of computation.\textsuperscript{12}

Remark 6.3. Ben-Sasson et al. [BSGH+05] also consider a family of problems about multivariate polynomials [BSGH+05, Definition 6.3]. We could have also considered a generalization to their definition, analogous to our Definition 6.1 that generalizes the univariate case [BSGH+05, Definition 6.1].

We choose to leave the investigation of such a definition (along with the possibility of finding even better reductions from natural problems “above” it, and better PCPs “below” it) for future work.

\textsuperscript{12}A technical difference of our Definition 6.1 compared to [BSGH+05, Definition 6.1] that is not a generalization is the form of the instance consistency check: in Definition 6.1, the instance consistency check is taken to be of a very specific form, namely, equality. This restriction simplifies our PCP construction for sACSP (discussed in Section 7). While we could construct (somewhat more complex) PCPs to account for an instance consistency check of a more general form (cf. Remark 7.7), we do not believe that such a gain in generality is justified, because this degree of freedom is not exploited in the reductions of Ben-Sasson et al. [BSCGT12].
7 A PCP for sACSP

We denote by \( V_{RS} \) and \( V_{VRS} \) two PCPP verifiers that respectively test proximity to RS and VRS over affine subspaces of finite field extensions of \( \mathbb{F}_2 \); we denote by \( P_{RS} \) and \( P_{VRS} \) their corresponding PCPP provers.

In this section we show how to use these four algorithms to construct a PCP system \((P_{sACSP}, V_{sACSP})\) for the language sACSP\((\text{par})\), for a given choice \( \text{par} \) of parameters.

When this construction is instantiated with our constructions of \( V_{RS} \) and \( V_{VRS} \) (cf. Algorithm 13 and Algorithm 12 and their soundness analysis in Section 10) and \( P_{RS} \) and \( P_{VRS} \) (cf. Algorithm 4 and Algorithm 3), we obtain a PCP system with quasilinear-time prover and succinct verifier (that only depends quasilinearly on the input instance). This PCP system is used in the proof of Theorem 1 in Section 5.

7.1 The Construction At High Level

Our construction follows and extends the one of Ben-Sasson and Sudan [BSS08]. Concretely, Ben-Sasson and Sudan showed how to test proximity to the Reed-Solomon code over additive subgroups of extension fields of \( \mathbb{F}_2 \) with quasilinear-size proximity proofs; using these, they then showed how to construct PCPs of quasilinear size for an algebraic constraint satisfaction problem that is a special case of sACSP, for the case where the verifier does not have to be succinct in time and without studying the prover complexity. Later, Ben-Sasson et al. [BSGH+05] developed techniques that allow the verifier in [BSS08] to run succinctly. (See Remark 7.9 for more details.)

As in [BSGH+05], we also need to ensure the succinctness of the verifier even if we ask the verifier to probabilistically check membership in sACSP\((\text{par})\), which involves probabilistically-checking properties of univariate polynomials with huge degrees.\(^{13}\) Moreover, we also need to ensure that the verifier does not perform expensive computations on \( F \), the “explicit” input (circuit descriptor) at hand. Furthermore, in our case we also need to ensure that the prover also runs very fast.

We extend and improve [BSS08, BSGH+05] as follows:

- We use additive FFT techniques [Mat08] and computational properties of linearized polynomials to construct a generalization of the PCPP verifiers for Reed-Solomon codes of [BSS08] (together with a tighter soundness analysis that will allow us to show much better concrete efficiency, as was discussed in Section 2.3) where the prover runs in quasilinear time and the verifier runs succinctly.

- Given a Reed-Solomon proximity testing system such as the one discussed in the previous bullet, we show how to construct a PCP system for sACSP\((\text{par})\) where, roughly, the prover runs in \( T \cdot \text{poly}(T) \) time and the verifier runs in \( |x| \cdot \text{polylog}(T) \) time. The definition of sACSP will ensure that the verifier is able to succinctly generate appropriate representations for all the relevant objects (such as a small arithmetic circuit computing the constraint polynomial \( P_T \)) as well as providing the appropriate additive subgroup structure necessary to leverage the proximity testing machinery for Reed-Solomon over sets with such a structure.

\(^{13}\)This, for example, is a difficulty that usually does not arise within algebraic PCPs using multivariate techniques; however such techniques are not known to yield quasilinear-size proofs (but only almost-linear [MR08]).
The construction is roughly as follows.

First recall from Section 6 that in order to verify whether a given instance \((x, T)\) is a member in \(\text{sACSP}(\text{par})\), for a given choice of parameters \(\text{par}\), one needs to establish whether there is a low-degree assignment polynomial \(A\) that satisfies two conditions: (i) when “composed” with the constraint polynomial \(P_T\), \(A\) vanishes everywhere on \(H_T\); and, moreover, (ii) \(A\) is “consistent” with \(x\).

To check the first condition, the PCP verifier \(V_{\text{sACSP}}\) works as follows. The verifier \(V_{\text{sACSP}}\) asks the prover to provide an evaluation \(p_0\) of \(A\) along with a proximity proof \(\pi_0\), in order to test proximity of \(p_0\) to the appropriate Reed-Solomon code by invoking \(V_{\text{RS}}\). The verifier \(V_{\text{sACSP}}\) also asks the prover to provide an evaluation \(p_1\) of \(B\), the polynomial that one obtains when composing \(A\) with \(P_T\), along with a proximity proof \(p_1\), in order to test proximity of \(p_1\) to the appropriate Vanishing Reed-Solomon code on the affine subspace \(H_T\) by invoking \(V_{\text{RS}}\). After this, the verifier \(V_{\text{sACSP}}\) performs a consistency check between \(p_0\) and \(p_1\) by verifying that the correct relation (i.e., as dictated by \(P_T\)) holds between \(p_0\) and \(p_1\).

To check the second condition, the verifier \(V_{\text{sACSP}}\) works as follows. The verifier \(V_{\text{sACSP}}\) asks the prover to further provide a proximity proof \(\pi_1\) for the proximity of \(p_0 - p_x\) to an appropriate Vanishing Reed-Solomon code on the \((\log |x|)\)-th affine subspace in \(\tilde{I}_T\), where \(p_x\) is a function depending on \(x\) that can be easily evaluated by the verifier. Intuitively, this will ensure that \(p_0\) takes on the bits of \(x\), as required, on the \((\log |x|)\)-th affine subspace in \(\tilde{I}_T\). (In our case, \(x\) will be the circuit description \(F\) which is given as input to the random-access machine.) The fact that consistency with the instance is done on an affine subspace is important to ensure that the prover and verifier can run in time quasilinear in the instance size.

Thus, the PCP prover \(P_{\text{sACSP}}\), on input the witness polynomial \(A\), will produce a PCP oracle \(\pi\) consisting of two pairs of strings \((p_0, \pi_0)\) and \((p_1, \pi_1)\) and a third string \(\pi_c\) such that:

- \((p_0, \pi_0)\) is a pair consisting of an implicit input and a proximity proof attesting to the fact that \(A\) is of low-enough degree; concretely, \(p_0\) is the evaluation table of \(A\) and \(\pi_0\) is a proximity proof of \(p_0\) to a Reed-Solomon code with appropriate parameters;

- \((p_1, \pi_1)\) is a pair consisting of an implicit input and a proximity proof attesting to the fact that the polynomial \(B\) computed from \(A\) and \(P_T\) is of low-enough degree and vanishes on \(H_T\); concretely, \(p_1\) is the evaluation table of \(B\) and \(\pi_1\) is a proximity proof of \(p_1\) to a Vanishing Reed-Solomon code with appropriate parameters;

- \(\pi_c\) is a proximity proof attesting to the fact that \(p_0 - p_x\), where \(p_x\) is a function depending on the input \(x\), is of low-enough degree and vanishes on the \((\log |x|)\)-th affine subspace in \(\tilde{I}_T\).

### 7.2 The Construction In Detail

Formally, we prove the following theorem:

**Theorem 7.1** (PCPs for \(\text{sACSP}\)). Fix the language \(\text{sACSP}\) with a choice of parameters given by

\[
\text{par} = \left( f, (m_H, t_H, \text{H}), (c_N, t_N, s_N, \text{N}), (t_P, s_P, \text{P}), (t_I, \text{I}) \right).
\]

There exists a PCP system \((P_{\text{sACSP}}, V_{\text{sACSP}})\) for \(\text{sACSP}(\text{par})\) with perfect completeness and soundness \(1/2\). Moreover:
\begin{itemize}
    \item *\( P_{\text{ACSP}} \) runs in sequential time
        \[
        \text{setup}_s(1^t) + \left( |x| + \left( s_P(1^t) + \sum_{i=1}^{c_N(1^t)} s_N(1^t, i) \right) \cdot 2^{f(1^t)} \right) \cdot \text{poly}(f(t))
        \]
        and parallel time \( \text{setup}_p(1^t) + O(f(t)^2) \).
    \item *\( V_{\text{ACSP}} \) runs in sequential time
        \[
        \text{setup}_s(1^t) + \left( |x| \cdot \left( \sum_{i=1}^{c_N(1^t)} \deg(N_{t,i}) \right) + \left( s_P(1^t) + \sum_{i=1}^{c_N(1^t)} s_N(1^t, i) \right) \right) \cdot \text{poly}(f(t))
        \]
        and parallel time \( \text{setup}_p(1^t) + O(f(t)^2) \).
\end{itemize}

Above, \( \text{setup}_s(1^t) \) is the setup sequential time to instantiate the parameters with index \( t \) and equals
\[
\text{time}_{\text{FindIrreduciblePoly}}(f(t)) + t_H(1^t) + \sum_{i=1}^{c_N(1^t)} t_N(1^t, i) + t_P(1^t) + t_I(1^t, 1^{\log |x|}) ,
\]
where \( \text{time}_{\text{FindIrreduciblePoly}}(f(t)) \) is the time for generating an irreducible polynomial of degree \( f(t) \) (cf. Algorithm 17); \( \text{setup}_p(1^t) \) is the corresponding setup parallel time.

**Remark 7.2.** For “natural” choices of parameters \( \text{par} \) (e.g., those generated by the reductions of Ben-Sasson et al. [BSCGT12] from random-access machines),
\[
\text{setup}_s(1^t) = s_P(1^t) \cdot \text{poly}(f(t)) \\
\text{setup}_p(1^t) = O(f(t)^2) ,
\]
\[
\sum_{i=1}^{c_N(1^t)} \deg(N_{t,i}) = \text{poly}(f(t)) ,
\]
\[
\sum_{i=1}^{c_N(1^t)} s_N(1^t, i) = \text{poly}(f(t)) ,
\]

In such a case, recalling that \( |x| \leq 2^t \leq 2^{f(1^t)} \),
\begin{itemize}
    \item *\( P_{\text{ACSP}} \) runs in sequential time \( s_P(1^t) \cdot 2^{f(1^t)} \cdot \text{poly}(f(t)) \) and parallel time \( O(f(t)^2) \),
    \item *\( V_{\text{ACSP}} \) runs in sequential time \( (|x| + s_P(1^t)) \cdot \text{poly}(f(t)) \) and parallel time \( O(f(t)^2) \).
\end{itemize}

Moreover, the degree of the field extension \( f(t) \) (which induces the corresponding field size \( 2^{f(1^t)} \)) is the main measure of complexity, since usually \( s_P(1^t) = \text{poly}(f(t)) \).

We recall that in Appendix B we give a complete and detailed algorithmic specification for \((P_{\text{ACSP}}, V_{\text{ACSP}})\). To the best of our knowledge, this is the first explicit construction of a PCP.
system with short proofs (and, in our case, fast provers) and succinct verifiers, and provides a valuable starting point for studying the efficiency of PCPs from a practical perspective.\footnote{We shall not conduct in this paper a detailed analysis of the proof time and space complexities and the verifier time and space complexities. While the algorithms that we present in Appendix B will fulfill the promise of a quasilinear-time prover and polylogarithmic-time verifier (with small exponents “in the polylog” and quasilinear running time in the input instance), we believe that a detailed analysis of these performance measures is best studied when accompanied with a code implementation. Instead, in this paper, we shall concentrate on giving a detailed analysis of the query complexity, randomness complexity, and proof length; we do so in Appendix C.}

In this section, we give the construction of \((P_{sACSP}, V_{sACSP})\), in terms of \(V_{RS}\) and \(V_{VRS}\) and their corresponding provers \(P_{RS}\) and \(P_{VRS}\), and then prove its completeness and soundness properties. (More precisely, we shall use the “amplified versions” \(V_{RS}\) and \(V_{VRS}\) of \(V_{RS}\) and \(V_{VRS}\) that allow us to control the proximity and soundness parameters; see Remark 10.2, and Algorithm 11 and Algorithm 10 for more details.)

**Details for PCP system construction.** We now give the details for the construction of the PCP system:

- in Construction 7.3 we describe the PCP prover \(P_{sACSP}\);
- in Definition 7.4 we define the “format” of the PCP oracle, and
- in Construction 7.5 we describe the PCP verifier \(V_{sACSP}\).

Concise pseudo-code listings for the PCP prover \(P_{sACSP}\) and PCP verifier \(V_{sACSP}\) can also be found in Algorithm 2 and Algorithm 9 respectively. The PCP prover \(P_{sACSP}\) for sACSP is as follows:

**Construction 7.3 (PCP Prover for sACSP).** The PCP prover for sACSP, with respect to a choice

\[ \text{par} = \left( f, (m_H, t_H, H), (c_N, t_N, s_N, N), (t_P, s_p, P), (t_I, I) \right) \]

of parameters, is denoted \(P_{sACSP}\) and has hard-coded in it this choice of parameters. On input an instance \((x, 1^t)\) and an assignment polynomial \(A: \mathbb{F}_t \rightarrow \mathbb{F}_t\) that is a witness to the membership of \((x, 1^t)\) in sACSP (see Definition 6.1), the PCP prover \(P_{sACSP}\) performs the following steps:

1. **Parameter instantiation:**
   - (a) Generate the field extension \(\mathbb{F}_t\) of \(\mathbb{F}_2\): compute the degree \(f(t)\), then compute the irreducible polynomial \(I_t := \text{FindIrreduciblePoly}(1^f(t))\) with a root \(x\), and let \(\mathbb{F}_t := \mathbb{F}_2(x)\). (See Parameter 1 in Definition 6.1.) A basis for \(\mathbb{F}_t\) is given by \(B_{\mathbb{F}_t} := (1, x, \ldots, x^{f(t)-1})\).
   - (b) Find the basis and offset for the affine subspace \(H_t\) of \(\mathbb{F}_t\) by computing \((B_{H_t}, O_{H_t}) := \text{FindH}(1^t)\). (See Parameter 3 in Definition 6.1.)
   - (c) Find the polynomials \((N_{t,i}(x))_{i=1}^{c_N(t)}\) that induce the “neighborhood” of each element in \(\mathbb{F}_t\): for \(i = 1, \ldots, c_N(t)\), compute \([N_{t,i}]^h := \text{FindN}(1^t, i)\). (See Parameter 5 in Definition 6.1.)
   - (d) Find the constraint polynomial by computing \([P_t]^h := \text{FindP}(1^t)\). (See Parameter 7 in Definition 6.1.)
   - (e) Find the basis and offset for the \((\log |x|)\)-th affine subspace \(I_{t, \log |x|}\) in \(\tilde{I}_t\) by computing \((B_{I_{t, \log |x|}}, O_{I_{t, \log |x|}}) := \text{FindI}(1^t, 1^{\log |x|})\). (See Parameter 9 in Definition 6.1.)

2. **Generate a proof that \(A\) has low degree:**
(a) Let \( p_0 \) be the evaluation table of \( A \) on \( \mathbb{F}_t \):
\[
p_0 := \left\{ (\alpha, A(\alpha)) : \alpha \in \mathbb{F}_t \right\}.
\]
(b) Compute a proof of proximity \( \pi_0 \) for \( p_0 \) to \( \text{RS}(\mathbb{F}_t, \mathbb{F}_t, 2^{\text{mH}(t)} - 1) \):
\[
\pi_0 := P_{\text{RS}}\left( I_t, B_{\mathbb{F}_t}, 0, 2^{\text{mH}(t)} - 1, A \right).
\]

3. Generate a proof that \( A \) satisfies the constraint polynomial:
   (a) Define the polynomial \( B(x) := P_t(x, A(N_t,1(x)), \ldots, A(N_t,\epsilon_{N(t)}(x))) \).
   (b) Let \( p_1 \) be the evaluation table of \( B \) on \( \mathbb{F}_t \):
\[
p_1 := \left\{ (\alpha, B(\alpha)) : \alpha \in \mathbb{F}_t \right\}.
\]
   (c) Define \( d := \text{deg}(P_t(x, x^{(2^{\text{mH}(t)}-1)-\text{deg}(N_t,1)}, \ldots, x^{(2^{\text{mH}(t)}-1)-\text{deg}(N_t,\epsilon_{N(t)})})) \).
   (d) Compute a proof of proximity \( \pi_1 \) for \( p_1 \) to \( \text{VRS}(\mathbb{F}_t, \mathbb{F}_t, H_t, d) \):
\[
\pi_1 := P_{\text{VRS}}\left( I_t, B_{\mathbb{F}_t}, 0, B_{H_t}, O_{H_t}, d, B \right).
\]

4. Generate a proof that \( A \) is consistent with \((x, 1^t)\):
   (a) Define \( A_x \) to be the low-degree extension of the function \( f_x : I_{t,\text{log}|x|} \rightarrow \{0, 1\} \) defined by \( f_x(\alpha_i) := x_i \) where \( \alpha_i \) is the \( i \)-th element in \( I_{t,\text{log}|x|} \).
   (b) Define \( A' := A - A_x \).
   (c) Compute a proof of proximity \( \pi_c \) for the evaluation of \( A' \) to \( \text{VRS}(\mathbb{F}_t, \mathbb{F}_t, I_{t,\text{log}|x|}, 2^{\text{mH}(t)} - 1) \):
\[
\pi_c := P_{\text{VRS}}\left( I_t, B_{\mathbb{F}_t}, 0, B_{H_t,\text{log}|x|}, O_{I_{t,\text{log}|x|}}, 2^{\text{mH}(t)} - 1, A' \right).
\]

5. Set \( \pi := (p_0, \pi_0, p_1, \pi_1, \pi_c) \) and output \( \pi \).

The PCP prover \( P_{\text{sACSP}} \) from Construction 7.3 allows us to define the format of a PCP proof for membership into the language sACSP:

**Definition 7.4 (PCP Proof for sACSP).** A PCP proof of membership into sACSP, with respect to a choice
\[
\text{par} = \left( f, (m_h, t_h, H), (c_n, t_n, s_n, N, t_p, s_p, P), (t_i, I) \right)
\]
of parameters, for an instance \((x, 1^t)\) is a string \( \pi = (p_0, \pi_0, p_1, \pi_1, \pi_c) \), where:

1. \( p_0 : \mathbb{F}_t \rightarrow \mathbb{F}_t \) is a function,
2. \( \pi_0 \) is a proof of proximity for \( p_0 \) to \( \text{RS}(\mathbb{F}_t, \mathbb{F}_t, 2^{\text{mH}(t)} - 1) \),
3. \( p_1 : \mathbb{F}_t \rightarrow \mathbb{F}_t \) is a function,
4. \( \pi_1 \) is a proof of proximity for \( p_1 \) to \( \text{VRS}(\mathbb{F}_t, \mathbb{F}_t, H_t, d) \) where the degree bound \( d \) is defined by \( d := \text{deg}(P_t(x, x^{(2^{\text{mH}(t)}-1)-\text{deg}(N_t,1)}, \ldots, x^{(2^{\text{mH}(t)}-1)-\text{deg}(N_t,\epsilon_{N(t)})})) \), and
5. \( \pi_c \) is a proof of proximity for \( p_0 - p_x \) to \( \text{VRS}(\mathbb{F}_t, \mathbb{F}_t, I_{t,\text{log}|x|}, 2^{\text{mH}(t)} - 1) \), where \( p_x \) is the low-degree extension of \( x \) over \( I_{t,\text{log}|x|} \) and \( I_{t,\text{log}|x|} \) is the \((\log|x|)\)-th affine subspace in \( I_t \).

The PCP verifier \( V_{\text{sACSP}} \) for sACSP is as follows:
Construction 7.5 (PCP Verifier for sACSP). The PCP verifier for sACSP, with respect to a choice
\[ \text{par} = \left( f, (m_H, t_H, H), (c_N, t_N, s_N, N), (t_p, s_p, P), (t_1, I) \right) \]
of parameters, is denoted \( V_{\text{sACSP}} \) and has hard-coded in it this choice of parameters. On input an instance \((x, t^i)\) and with oracle access to a proof \( \pi \) following the format of Definition 7.4, the verifier \( V_{\text{sACSP}} \) does the following:

1. **Parameter instantiation:**
   (a) Generate the field extension \( F_t \) of \( F_2 \); compute the degree \( f(t) \), then compute the irreducible polynomial \( I_t := \text{FindIrrPoly}\left(1^{f(t)}\right) \) with a root \( x \), and let \( F_t := F_2(x) \). (See Parameter 1 in Definition 6.1.) A basis for \( F_t \) is given by \( B_{\bar{g}_t} := (1, x, \ldots, x^{f(t)-1}) \).
   (b) Find the basis and offset for the affine subspace \( H_t \) of \( F_t \) by computing \( (B_{H_t}, O_{H_t}) := \text{FindH}(1^t) \). (See Parameter 3 in Definition 6.1.)
   (c) Find the polynomials \( \left( N_{t,i}(x) \right)_{i=1}^{c_N(t)} \) that induce the “neighborhood” of each element in \( F_t \); for \( i = 1, \ldots, c_N(t) \), compute \( [N_{t,i}]^\alpha := \text{FindN}(1^t, i) \). (See Parameter 5 in Definition 6.1.)
   (d) Find the constraint polynomial by computing \( [P_t]^\alpha := \text{FindP}(1^t) \). (See Parameter 7 in Definition 6.1.)
   (e) Find the basis and offset for the \((\log |x|)\)-th affine subspace \( I_{t,\log|\mathbf{x}|} \) in \( \bar{I}_t \) by computing \( (B_{I_{t,\log|\mathbf{x}|}}, O_{I_{t,\log|\mathbf{x}|}}) := \text{FindI}(1^t, 1^{\log|\mathbf{x}|}) \). (See Parameter 9 in Definition 6.1.)

2. **Proximity of \( p_0 \) to RS:**
   Invoke the (already “amplified”) PCPP-verifier \( V_{\text{RS}} \) for the Reed-Solomon code, with proximity parameter \( \delta_{\text{RS}} := \left(8 \sum_{i=1}^{c_N(t)} \deg(N_{t,i})\right)^{-1} \) and soundness \( s'_{\text{RS}} := 1/2 \), on explicit input \((F_t, F_t, 2^m_{\text{H}(t)} - 1)\), implicit input \( p_0 \), and proof of proximity \( \pi_0 \); that is, verify that
   \[ V_{\text{RS}}^{\langle p_0, \pi_0 \rangle}(B_{\bar{F}_t}, B_{\bar{F}_t}, 0_{\bar{F}_t}, 2^m_{\text{H}(t)} - 1, \delta_{\text{RS}}, s'_{\text{RS}}) \]
   accepts.

3. **Proximity of \( p_1 \) to VRS:**
   Invoke the (already “amplified”) PCPP-verifier \( V_{\text{VRS}} \) for the Vanishing Reed-Solomon code, with proximity parameter \( \delta_{\text{VRS}} := 1/8 \) and soundness \( s'_{\text{VRS}} := 1/2 \), on explicit input \((F_t, F_t, H_t, d)\), implicit input \( p_1 \), and proof of proximity \( \pi_1 \); that is, verify that
   \[ V_{\text{VRS}}^{\langle p_1, \pi_1 \rangle}(B_{\bar{F}_t}, B_{\bar{F}_t}, 0_{\bar{F}_t}, B_{H_t}, O_{H_t}, d, \delta_{\text{VRS}}, s'_{\text{VRS}}) \]
   accepts. Here \( d := \deg(P_t(x, x^{(2^m_{\text{H}(t)} - 1)\deg(N_{t,1})}, \ldots, x^{(2^m_{\text{H}(t)} - 1)\deg(N_{t,c_N(t)})})) \).

4. **Consistency between \( p_0 \) and \( p_1 \):**
   (a) Draw a random \( \alpha \in F_t \).
   (b) For \( i = 1, \ldots, c_N(t) \), compute \( \alpha_i := [N_{t,i}]^\alpha(\alpha) \).
   (c) Query \( p_0 \) at the following points: \( \alpha_1, \ldots, \alpha_{c_N(t)} \).
   (d) Query \( p_1 \) at the point \( \alpha \).
   (e) Compute \( [P_t]^\alpha := \text{FindP}(1^t) \).
   (f) Compute \( \omega := [P_t]^\alpha(\alpha, p_0(\alpha_1), \ldots, p_0(\alpha_{c_N(t)})) \).
(g) Verify that \( p_1(\alpha) = \omega \).

5. **Consistency of \( p_0 \) with the instance \((x, 1^t)\):**

Define \( A_x \) to be the low-degree extension of the function \( f_x: I_{\log |x|} \rightarrow \{0, 1\} \) defined by \( f_x(\alpha_i) := x_i \) where \( \alpha_i \) is the \( i \)-th element in \( I_{\log |x|} \) and \( I_{\log |x|} \) is the \((\log |x|)\)-th affine subspace in \( \bar{F}_t \); let \( p_0 \) be the evaluation of \( A_x \) on \( \bar{F}_t \).

Invoke the (already “amplified”) PCPP-verifier \( V_{\text{aVRS}} \) for the vanishing Reed-Solomon code, with proximity parameter \( \delta_c := (8\sum_{t=1}^{\log(t)} \deg(N_{t,i}))^{-1} \) and soundness \( s'_{RS} := 1/2 \), on explicit input \( (\bar{F}_t, \bar{F}_t, I_{\log |x|}, 2^{mH(t)} - 1) \), implicit input \( p_0 - p_x \), and proof of proximity \( \pi_c \); that is, verify that

\[
V_{\text{aVRS}}^{(p_0-p_x, \pi_c)}(\bar{B}_F, \bar{B}_{\bar{F}_t}, 0_{\bar{F}_t}, \bar{B}_{H_{\log |x|}}, \bar{O}_{I_{\log |x|}}, 2^{mH(t)} - 1, \delta_c, s'_{c})
\]

accepts.

Now we prove the correctness of the above constructions:

**Proof of Theorem 7.1.** We prove that the PCP verifier \( V_{\text{aACSP}} \) from Construction 7.5 has perfect completeness and soundness \( 1/2 \), and, moreover, that the PCP prover \( P_{\text{aACSP}} \) from Construction 7.3, when provided with a valid witness, fulfills the perfect completeness of \( V_{\text{aACSP}} \). The analysis of the query complexity, randomness complexity, and proof length complexity of the PCP system \((P_{\text{aACSP}}, V_{\text{aACSP}})\) is given in Appendix C (cf. Lemma C.8).

**Completeness.** We begin by proving that \( V_{\text{aACSP}} \) has perfect completeness. So suppose that \((x, 1^t) \in \text{sACSP}\), and let \( A: \bar{F}_t \rightarrow \bar{F}_t \) be an assignment polynomial that witnesses this.

Let \( p_0: \bar{F}_t \rightarrow \bar{F}_t \) be the evaluation on \( \bar{F}_t \) of the assignment polynomial \( A \). Recall that, by Definition 6.1, the degree of \( A \) is at most \( 2^{mH(t)} \); hence, \( p_0 \in \text{RS}(\bar{F}_t, \bar{F}_t, 2^{mH(t)} - 1) \).

Invoking the completeness property of the PCPP-verifier \( V_{\text{aRS}} \), we deduce that there exists a string \( \pi_0 \) that makes \( V_{\text{aRS}}^{(p_0, \pi_0)}(\bar{B}_F, \bar{B}_{\bar{F}_t}, 0_{\bar{F}_t}, 2^{mH(t)} - 1, \delta_{RS}, s'_{RS}) \) accept with probability 1. We conclude that the same string \( \pi_0 \) makes the first subtest of \( V_{\text{aACSP}} \) accept with probability 1, because the first subtest of \( V_{\text{aACSP}} \) is the test \( V_{\text{aRS}}^{(p_0, \pi_0)}(\bar{B}_F, \bar{B}_{\bar{F}_t}, 0_{\bar{F}_t}, 2^{mH(t)} - 1, \delta_{RS}, s'_{RS}) \). (See Step 2 of \( V_{\text{aACSP}} \).)

Let \( p_1: \bar{F}_t \rightarrow \bar{F}_t \) be the evaluation on \( \bar{F}_t \) of the polynomial \( B: \bar{F}_t \rightarrow \bar{F}_t \) defined as follows:

\[
B(x) := P_1\left(x, A(N_{1,1}(x)), \ldots, A(N_{t,cN(t)}(x))\right).
\]

Notice that the degree of \( B \) can be upper bounded as follows:

\[
\deg(B) \leq d := \deg(P_1(x, x'(2^{mH(t)} - 1) \cdot \deg(N_{1,1}), \ldots, x'(2^{mH(t)} - 1) \cdot \deg(N_{t,cN(t)})))
\]

furthermore, because \( A \) is a witness for \((x, 1^t) \in \text{sACSP}\), due to Item (i) in Definition 6.1, we know that \( B \) vanishes on the affine subspace \( H_t \); hence, \( p_1 \in \text{VRS}(\bar{F}_t, \bar{F}_t, H_t, d) \). Invoking the completeness property of the PCPP-verifier \( V_{\text{aVRS}} \), we deduce that there exists a string \( \pi_1 \) that makes \( V_{\text{aVRS}}^{(p_1, \pi_1)}(\bar{B}_F, \bar{B}_{\bar{F}_t}, 0_{\bar{F}_t}, \bar{B}_{H_t}, \ubar{O}_{H_t}, d, \delta_{VRS}, s'_{VRS}) \) accept with probability 1. We conclude that the same string \( \pi_1 \) makes the second subtest of \( V_{\text{aACSP}} \) accept with probability 1, because the second subtest of \( V_{\text{aACSP}} \) is the test \( V_{\text{aVRS}}^{(p_1, \pi_1)}(\bar{B}_F, \bar{B}_{\bar{F}_t}, 0_{\bar{F}_t}, \bar{B}_{H_t}, \ubar{O}_{H_t}, d, \delta_{VRS}, s'_{VRS}) \). (See Step 3 of \( V_{\text{aACSP}} \).)
Moreover, by construction of \( p_0 \) and \( p_1 \), for every \( \alpha \in \mathbb{F}_t \),

\[
p_1(\alpha) = B(\alpha) = P_t \left( \alpha, A(N_t,1(\alpha)), \ldots, A(N_t,\infty(t)(\alpha)) \right) = P_t \left( \alpha, p_0(N_t,1(\alpha)), \ldots, p_0(N_t,\infty(t)(\alpha)) \right)
\]

so that the third subtest of \( V_{\text{sACSP}} \) succeeds with probability 1. (See Step 4 of \( V_{\text{sACSP}} \).)

Finally, because \( A \) is a witness for \( (x,1^t) \in \text{sACSP} \), due to Item (ii) in Definition 6.1, we know that \( A \) is consistent with the instance \( (x,1^t) \), i.e., we know that \( A(\alpha_i) = x_i \) for \( i = 1, \ldots, |x| \), where \( \alpha_i \) is the \( i \)-th element of \( I_t, \log |x| \) and \( I_t, \log |x| \) is the \( (\log |x|) \)-th affine subspace in \( \tilde{I} \). Hence, letting \( A_x \) be the low-degree extension of the function \( f_x: I_t, \log |x| \rightarrow \{0,1\} \) defined by \( f_x(\alpha_i) := x_i \) where \( \alpha_i \) is the \( i \)-th element in \( I_t, \log |x| \), and \( p_x \) the evaluation of \( A_x \) on \( \mathbb{F}_t \), we know that \( p_0 - p_x \) is in \( \text{VRS}(\mathbb{F}_t, \mathbb{F}_t, I_t, \log |x|, 2^{m_H(t)} - 1) \). Once again invoking the completeness property of the PCPP verifier \( V_{\text{VRS}} \), we deduce that there exists a string \( \pi_\varepsilon \) that makes \( V_{\text{VRS}}^p_0(\mathbb{F}_t, \mathbb{F}_t, 0, \mathbb{F}_t, I_t, \log |x|, \mathbb{F}_t, \log |x|, 2^{m_H(t)} - 1, \delta_c, s'_\varepsilon) \) accept with probability 1. We conclude that the same string \( \pi_\varepsilon \) makes the fourth subtest of \( V_{\text{sACSP}} \) accept with probability 1, because the fourth (and last) subtest of \( V_{\text{sACSP}} \) is simply the test \( V_{\text{sACSP}}^p_0(\mathbb{F}_t, \mathbb{F}_t, 0, \mathbb{F}_t, I_t, \log |x|, \mathbb{F}_t, \log |x|, 2^{m_H(t)} - 1, \delta_c, s'_\varepsilon) \). (See Step 5 of \( V_{\text{sACSP}} \).)

Thus, we have established that \( V_{\text{sACSP}} \) has perfect completeness.

Finally, note that the PCP prover \( P_{\text{sACSP}} \), on input \( (x,1^t) \) and \( A \), does indeed construct a proof \( \pi = (p_0, \pi_1, p_1, \pi_1, \pi_\varepsilon) \) that makes \( V_{\text{sACSP}} \) accept with probability 1 — by providing the correct evaluation tables \( p_0 \) and \( p_1 \) and running the PCPP provers for RS and VRS with the appropriate inputs.

**Soundness.** Next, we prove that \( V_{\text{sACSP}} \) has soundness \( 1/2 \). As before, let \( I_t, \log |x| \) be the \( (\log |x|) \)-th affine subspace in \( \tilde{I} \), \( A_x \) be the low-degree extension of the function \( f_x: I_t, \log |x| \rightarrow \{0,1\} \) defined by \( f_x(\alpha_i) := x_i \) where \( \alpha_i \) is the \( i \)-th element in \( I_t, \log |x| \), and \( p_x \) the evaluation of \( A_x \) on \( \mathbb{F}_t \). Also let \( d := \deg(P(x, x^{(2^{\mu_H(t)} - 1)\deg(N_t,1)}, \ldots, x^{(2^{\mu_H(t)} - 1)\deg(N_t,\infty(t))})) \).

Suppose that \( (x,1^t) \notin \text{sACSP} \). We distinguish between four cases:

- **Case 1:** the function \( p_0 \) is \( (8 \sum_{i=1}^{\infty(t)} \deg(N_{t,i}))^{-1} \)-far from \( \text{RS}(\mathbb{F}_t, \mathbb{F}_t, 2^{m_H(t)} - 1) \).
  Recall that the first subtest of \( V_{\text{sACSP}} \) (Step 2) tests proximity of \( p_0 \) to \( \text{RS}(\mathbb{F}_t, \mathbb{F}_t, 2^{m_H(t)} - 1) \) using the (amplified) RS verifier \( V_{\text{RS}} \) with proximity parameter \( \delta_{\text{RS}} = (8 \sum_{i=1}^{\infty(t)} \deg(N_{t,i}))^{-1} \) and soundness \( s'_{\text{RS}} = 1/2 \); thus, in this case the first subtest of \( V_{\text{sACSP}} \) rejects with probability at least \( 1/2 \).

- **Case 2:** the function \( p_1 \) is \( 1/8 \)-far from \( \text{VRS}(\mathbb{F}_t, \mathbb{F}_t, H_t, d) \).
  Recall that the second subtest of \( V_{\text{sACSP}} \) (Step 3) tests proximity of \( p_1 \) to \( \text{VRS}(\mathbb{F}_t, \mathbb{F}_t, H_t, d) \) using the (amplified) VRS verifier \( V_{\text{VRS}} \) with proximity parameter \( \delta_{\text{VRS}} = 1/8 \) and soundness \( s'_{\text{VRS}} = 1/2 \); thus, in this case the second subtest of \( V_{\text{sACSP}} \) rejects with probability at least \( 1/2 \).

- **Case 3:** the function \( p_0 - p_x \) is \( (8 \sum_{i=1}^{\infty(t)} \deg(N_{t,i}))^{-1} \)-far from \( \text{VRS}(\mathbb{F}_t, \mathbb{F}_t, I_t, \log |x|, 2^{m_H(t)} - 1) \).
  Recall that the fourth subtest of \( V_{\text{sACSP}} \) (Step 5) tests proximity of \( p_0 - p_x \) to \( \text{VRS}(\mathbb{F}_t, \mathbb{F}_t, I_t, \log |x|, 2^{m_H(t)} - 1) \) using the (amplified) VRS verifier \( V_{\text{VRS}} \) with probability parameter
\[ \delta_c = (8 \sum_{t=1}^{cN(t)} \deg(N_t, i))^{-1} \] and soundness \( s' = 1/2 \); thus, in this case the second subtest of \( V_{\text{ACSP}} \) rejects with probability at least \( 1/2 \).

- **Case 4:** neither of the above three cases hold.

Let \( A: \mathbb{F}_t \rightarrow \mathbb{F}_t \) be a polynomial of degree less than \( 2^{\text{mH}(t)} \) whose evaluation table over \( \mathbb{F}_t \) is closest to \( p_0 \), and let \( B: \mathbb{F}_t \rightarrow \mathbb{F}_t \) be the polynomial defined as \( B(x) := P_t(x, A(N_t, 1(x)), \ldots, A(N_t, \text{cN}(t)(x))) \). Note that \( A \) is unique, because \( 1 - (2^{\text{mH}(t)} - 1)/|\mathbb{F}_t| \) is larger than \( 2\delta_{\text{RS}} = (4 \sum_{i=1}^{\text{cN}(t)} \deg(N_t, i))^{-1} \). (See Lemma 4.11.)

Observe that \( p_0 - p_x = (8 \sum_{i=1}^{\text{cN}(t)} \deg(N_t, i))^{-1} \)-close to the evaluation table of \( A - A_x \) over \( \mathbb{F}_t \). Let \( A': \mathbb{F}_t \rightarrow \mathbb{F}_t \) be a polynomial of degree less than \( 2^{\text{mH}(t)} \) vanishing on \( I_{t, \log |x|} \) whose evaluation table over \( \mathbb{F}_t \) is closest to \( p_0 - p_x \). Note that \( A' = A - A_x \) because both \( A' \) and \( A - A_x \) are polynomials of degree less than \( 2^{\text{mH}(t)} \) that are \( (8 \sum_{i=1}^{\text{cN}(t)} \deg(N_t, i))^{-1} \)-close to \( p_0 - p_x \) and \( 1 - (2^{\text{mH}(t)} - 1)/|\mathbb{F}_t| \) is larger than \( (4 \sum_{i=1}^{\text{cN}(t)} \deg(N_t, i))^{-1} \). (See Lemma 4.11.) Thus we deduce that \( A \) is consistent with the instance \( (x, 1^t) \), i.e., satisfies Item (ii) in Definition 6.1.

Because \( p_0 \) is \( (8 \sum_{i=1}^{\text{cN}(t)} \deg(N_t, i))^{-1} \)-close to the evaluation table of \( A \) over \( \mathbb{F}_t \), we deduce that, for \( i = 1, \ldots, \text{cN}(t) \), \( p_0 \circ N_t, i \) is \( \frac{\deg(N_t, i)}{8 \sum_{i=1}^{\text{cN}(t)} \deg(N_t, i)} \)-close to the evaluation table of \( A \circ N_t, i \).

Define the function \( p_2: \mathbb{F}_t \rightarrow \mathbb{F}_t \) by

\[ p_2(x) := P_t(x, p_0(N_t, 1(x)), \ldots, p_0(N_t, \text{cN}(t)(x))) \]

We deduce then, via a union bound, that \( p_2 \) must be \( 1/8 \)-close to the evaluation table of \( B(x) \) over \( \mathbb{F}_t \).

Now let \( B': \mathbb{F}_t \rightarrow \mathbb{F}_t \) be a polynomial of degree at most \( d \) vanishing on \( H_t \) whose evaluation table over \( \mathbb{F}_t \) is closest to \( p_1 \). Again note that \( B' \) is unique, because \( 1 - d/|\mathbb{F}_t| \) is larger than \( 2\delta_{\text{VRS}} = 1/4 \). (See Lemma 4.11.) Now, \( B \) and \( B' \) must be distinct for, otherwise, \( B \) would vanish on \( H_t \), implying that \( A \) would satisfy the constraint polynomial \( P_t \), which would in turn imply (together with the fact that \( A \) is consistent with the instance \( (x, 1^t) \)) that \( (x, 1^t) \in s\text{ACSP} \) — a contradiction. Thus, since both \( B \) and \( B' \) are (distinct) polynomials of degree at most \( d \leq |\mathbb{F}_t|/4 \), their evaluation tables over \( \mathbb{F}_t \) may agree on at most a 1/4 fraction of their entries. Thus, by a union bound, the third subtest of \( V_{\text{ACSP}} \) (Step 4) accepts with probability at most \( 1/8 + 1/8 + 1/4 = 1/2 \).

This completes the proof of the soundness property.

**Remark 7.6.** More generally, the soundness analysis would have also worked for any proximity parameter \( \delta_{\text{RS}} \) for \( V_{\text{ars}} \) and proximity parameters \( \delta_{\text{VRS}} \) and \( \delta_c \) for \( V_{\text{VRS}} \) as long as the following conditions hold: letting \( d := \deg(P_t(x, x^{(2^{\text{mH}(t)} - 1)} \deg(N_t, 1), \ldots, x^{(2^{\text{mH}(t)} - 1)} \deg(N_t, \text{cN}(t)))) \),

\[
1 - \frac{2^{\text{mH}(t)} - 1}{|\mathbb{F}_t|} > 2\delta_{\text{RS}} \text{ , (to ensure uniqueness of } A \text{)}
\]
\[
1 - \frac{2^{\text{mH}(t)} - 1}{|\mathbb{F}_t|} > \delta_{\text{RS}} + \delta_c \text{ , (to ensure uniqueness of } A' \text{ and } A' = A - A_x \text{)}
\]
\[
1 - \frac{d}{|\mathbb{F}_t|} > 2\delta_{\text{VRS}} \text{ , (to ensure uniqueness of } B' \text{)}
\]
\[
\left( \varepsilon_{\mathcal{N}(t)} \right) \left( \sum_{i=1}^{\deg(N_{t,i})} \right) \delta_{\text{RS}} + \delta_{\text{VRS}} + \frac{d}{|\mathcal{F}|} \leq \frac{1}{2}.
\]

For example, for the specific choices of

\[
\delta_{\text{RS}} = \delta_c = \frac{1}{8} \sum_{i=1}^{\deg(N_{t,i})} \text{deg}(N_{t,i})
\]

\[
\delta_{\text{VRS}} = \frac{1}{8}
\]

that we used in the proof of Theorem 7.1, all of the above constraints are implied by the sACSP algebraic constraint from Equation 4 of Definition 6.1.

**Remark 7.7.** The consistency with the instance requirement in the definition of sACSP (i.e., Item (ii) of Definition 6.1) is quite “special”: it specifically requires that the concatenation of the vector of field elements \((A(\alpha_1), \ldots, A(\alpha_{|x|}))\) is, when properly converted to bits, equal to \(x\). This specific form of instance consistency enables us to use a simple test for verifying this requirement: namely, we can use a test of proximity to the appropriate Vanishing Reed-Solomon code. (See Step 5 of \(V_{\text{sACSP}}\).)

It is possible to extend our construction to support more general forms of instance consistency where, for example, we are given some predicate that takes as input both \(x\) and \((A(\alpha_1), \ldots, A(\alpha_{|x|}))\) and decides whether the two are “consistent” or not (via a criterion that is perhaps different than mere equality between the two). To support any such a predicate, we would need to (1) account for the complexity of the predicate when viewed as a polynomial when specifying constraints on the field size, and (2) perform tests that are more complicated than simply testing proximity to an appropriate Vanishing Reed-Solomon code and are instead similar to how we verify that the constraint polynomial \(P_t\) is satisfied. (However, such an extension would complicate the PCP construction without much justification; see Footnote 12.)

**Remark 7.8.** While the techniques used to construct the PCP for sACSP can be used to also construct a PCP of Proximity [DR04, BSGH+06] for sACSP, we do not work out the details.

For suppose that the instance \((x, 1^t)\) is such that \(x\) is long, and one wishes to separate an offline and online phases of a verifier, where during the offline phase the verifier may run in time proportional to \(|x|\), but not during the online phase. In such a case PCPPs could help. However, we believe that there is a solution that (only comes at the expense of assuming the existence of one-way functions and) is more convenient in many settings: one can invoke the Untrusted Input Lemma of Ben-Sasson et al. [BSCGT12].

Indeed, PCPs of Proximity have the disadvantage that one must have oracle access to the long input \(x\). Depending on the application, this may be quite inconvenient (especially if one wishes to conduct several computations on \(x\)). On the other hand, the reduction in [BSCGT12] allows one to “move the input \(x\) to the witness” and replace \(x\) with a much shorter digest of it (which can be reused across multiple computations). Moreover, from an efficiency standpoint, enhancing our construction to a PCP of Proximity would make it somewhat less efficient, whereas the reduction in [BSCGT12] is much lighter.

So from both a convenience and efficiency perspective, a reduction like that in [BSCGT12] seems to be preferable for the purposes of handling long inputs.

---

15Such an invocation requires the PCP to satisfy a knowledge property; we prove that this is the case for our PCPs in the proof of our Theorem 3.
Remark 7.9. Ben-Sasson and Sudan constructed PCPs for an algebraic constraint satisfaction problem [BSS08, Section 3.3.1], which they call ALGEBRAIC-CSP\textsubscript{k,d}, as part of the proof of their main theorem [BSS08, Theorem 2.2], which gives PCPs for \textsc{NTIME}(t) languages with quasilinear proof-length complexity and polylogarithmic randomness and query complexity. Our construction roughly follows their approach, but necessitates additional work for the PCP system to handle the more general language sACSP, to ensure that the verifier is succinct, and to ensure that the prover runs in quasilinear-time (and, moreover, that both verifier and prover run quasilinearly relative to the instance size).

The construction of this section implies as a special case a proof of a theorem left implicit in [BSGH+05], where a special case of the language sACSP was considered for the purpose of constructing succinct verifiers for the PCPs of Ben-Sasson and Sudan. As discussed before, in our case, we also need to concentrate on the construction of the prover (to ensure that it runs in quasilinear time) and the complexity of the prover and verifier in terms of the input instance (which we will also ensure is quasilinear). These concerns were not addressed before, and are ultimately crucial to prove our Theorem 1.

Remark 7.10 (combinatorial techniques). While the early results on PCPs exploited predominantly algebraic techniques [BFLS91, AS98, ALM+98], by now also a combinatorial proof is known [Din07]. However, despite the recent improvements in the understanding of verifier-efficient PCPs [Mei09], combinatorial techniques seem to still lag behind algebraic techniques in potential for practical PCPs. For example, it is still not known how to generate quasilinear-size PCP proofs using combinatorial techniques (though recent progress was shown by [Mei12]). Moreover, the current understanding of practical implementations of expander constructions and algorithmic implementations of graph operations does not seem stand up to the current understanding of efficient algebraic computation. Indeed, when it comes to polynomial arithmetic, we already possess a quite good understanding of how to multiply, evaluate, interpolate very fast in practice via FFT methods — such extensive algorithmic knowledge seems crucial for practical implementations of PCPs.
8 Proof of Theorem 2

In this section we prove Theorem 2, discussed in Section 1.3 and formally stated in Section 2.3. The theorem states the existence of a PCPP system (cf. Definition 2.5) for the code ensemble $E_{RS}$ (cf. Definition 2.9) having a concrete-efficiency threshold $\hat{B}_{RS} \leq 2^{35}$ (cf. Definition 2.7).

Recall that our proof strategy is in two steps; we describe these two steps in Section 8.1 and Section 8.2 respectively. We then concisely summarize the proof of the theorem in Section 8.3. Throughout, it will be useful to keep in mind the definitions from Section 4.

8.1 Step 1: Improving the Universal Constant of Bivariate Testing

The first step in our proof of Theorem 2 is to improve the value of the universal constant of bivariate testing. Let us explain.

Testing proximity to bivariate low-degree polynomials via a “random row or column test” is at the basis of the soundness analysis of the PCPP verifier for Reed-Solomon codes of Ben-Sasson and Sudan [BSS08] as well as of its generalization constructed and analyzed in this paper. Specifically, the soundness analysis of [BSS08] relied on the following fact:

**Lemma 8.1 ([BSS08, Lemma 6.12]).** Let $F$ be a field. There exists a universal constant $c_0$ such that the following holds: for every two finite subsets $A$ and $B$ of $F$, every two $d, e \geq 0$ with $d \leq |A|/4$ and $e \leq |B|/8$, and every function $g : A \times B \to F$, it is the case that

$$\delta^{(d,e)}_{A \times B}(g) \leq c_0 \cdot \left( \delta^{(d,e)}_{A \times B}(g) + \delta^{(e)}_{A \times B}(g) \right).$$

Recall that $\delta^{(d,e)}_{A \times B}(f)$, $\delta^{(e)}_{A \times B}(f)$, and $\delta^{(d,e)}_{A \times B}(f)$ respectively denote the distance of the function $f$ to bivariate polynomial evaluations over $A \times B$ with degree in $x$ at most $d$ (and arbitrary degree in $y$), degree in $y$ at most $e$ (and arbitrary degree in $x$), and degree in $x$ at most $d$ and in $y$ at most $e$. (See Definition 4.9.)

In other words, Lemma 8.1 says that testing proximity of a function $g : A \times B \to F$ to $RM(F, A \times B, (d, e))$, which is the Reed-Muller code over $A \times B$ of degree $(d, e)$ (cf. Definition 4.6), can be done by examining the values of $g$ over a random line in the first coordinate (i.e., a random “column”) and over a random line in the second coordinate (i.e., a random “row”). The lemma is a corollary to the Bivariate Testing Theorem of Polishchuk and Spielman [PS94][Spi95, Theorem 4.2.19].

The crucial aspect of Lemma 8.1 that ultimately allows for the construction of quasilinear-size proximity proofs in [BSS08] (via a recursive composition) is the fact that the fractional degree (i.e., the ratio of the degree over the domain size) in both coordinates is constant, that is, the domain size need only be a constant larger than the degree — this is unlike the corresponding theorem in [AS98] where the size of the domain had to quadratically depend on the degree.

Another aspect of Lemma 8.1, which is very important from our perspective of concrete efficiency, is the value of the universal constant of bivariate testing $c_0$: specifically, the smaller a value one can show for $c_0$ the better soundness one can show for testing proximity to the Reed-Solomon code and, thus, ultimately construct PCPs with better soundness. (We shall discuss this in more detail shortly, in Section 8.2.) In [BSS08], it was shown that one can take $c_0 = 128$. 

36
We show that one can take $c_0 = 10.24$. In fact, we state and prove the (improved) lemma of Ben-Sasson and Sudan in a more general form, letting $c_0$ depend on the fractional degree of each coordinate.

**Theorem 8.2** (improved universal constant of bivariate testing). Let $\mathbb{F}$ be a field. Let $d, m, e, n \in \mathbb{N}$ be such that $1 > \frac{d}{m} + \frac{e}{n} + 2\delta$ for some positive $\delta$. Define

$$c_0 := \max\left\{3, \inf \left\{\delta^{-2} : \delta > 0 \text{ and } 1 > \frac{d}{m} + \frac{e}{n} + 2\delta\right\}\right\}.$$  

Then, for every two finite subsets $A$ and $B$ of $\mathbb{F}$ of respective sizes $m$ and $n$ and every function $g: A \times B \to \mathbb{F}$, it is the case that

$$\delta_{A \times B}^{(d,e)}(g) \leq c_0 \cdot \left(\delta_{A \times B}^{(d,*)}(g) + \delta_{A \times B}^{(*,e)}(g)\right).$$

By setting $\frac{d}{m} := \frac{1}{4}$ and $\frac{e}{n} := \frac{1}{8}$ as in Lemma 8.1, we recover the (improved) constant $c_0 = 10.24$, as opposed to the previous value $c_0 = 128$.

The proof of the theorem is given in Section 9; it follows via improvements to the proof of [Spi95, Theorem 4.2.19] and its corollary Lemma 8.1.

The above lemma can now also be invoked with different settings of $\frac{d}{m}$ and $\frac{e}{n}$, other than the $\frac{d}{m} = \frac{1}{4}$ and $\frac{e}{n} = \frac{1}{8}$ originally used in Lemma 8.1. Different settings of $\frac{d}{m}$ and $\frac{e}{n}$, eventually correspond (as can be seen by inspecting how Theorem 8.2 is eventually invoked in the soundness analysis in Section 10) to changing the “rate” of the proof of proximity; for example, with $\frac{d}{m} = \frac{1}{8}$ and $\frac{e}{n} = \frac{1}{8}$, we obtain the smaller constant $c_0 = 64/9 \approx 7.1$ at the cost of decreasing the rate. More generally, it is possible to decrease $c_0$ further if one is willing to decrease either the ratio $\frac{d}{m}$ or $\frac{e}{n}$ (or both); doing so is possible, but will increase the length of the proof of proximity (i.e., decreasing the rate). The point is that the lemma stated in this way allows us to easily deduce what constant $c_0$ to use for different choices of rate; it will also enable us to find optimal choices of parameters for a given concrete problem size. Explicitly having these degrees of freedom will ultimately be crucial to enable us to find find a construction with a good concrete-efficiency threshold.

We believe that Theorem 8.2 can be further improved, and we believe it is an important open problem to do so: even small improvements (e.g., relaxing the requirement in the theorem from $1 > \frac{d}{m} + \frac{e}{n} + 2\delta$ to $2 > \frac{d}{m} + \frac{e}{n} + 2\delta$) eventually translate into tremendous improvements to the concrete-efficiency thresholds of PCPP systems for Reed-Solomon codes.

### 8.2 Step 2: Improving the Soundness Analysis of the Recursive Construction

In general, the verifier of a PCPP system consists of the sequential repetition of a simpler “basic” verifier, and the number of repetitions is inversely proportional to the soundness of this basic verifier; the soundness may be a function of various parameters. The second step in our proof of Theorem 2 is to provide a class of constructions that generalize the “basic” verifiers of [BSS08] and deduce for this class a much tighter and explicit soundness analysis. Obtaining as good a soundness as possible is critical for improving concrete efficiency, because worse (i.e., lower) soundness directly translates into a greater number of repetitions needed to bring the soundness up to, say, $1/2$; each repetition costs more queries, random coins, and, most importantly, running time.
Concretely, the second step of our theorem consists of much tighter soundness analyses for generalizations of the (strong) PCPP verifiers (cf. Definition 4.15) testing proximity to RS and VRS (cf. Definition 4.3 and Definition 4.4) constructed by Ben-Sasson and Sudan [BSS08] based on Lemma 8.1; we respectively denote these two PCPP verifiers by \( V_{RS} \) and \( V_{VRS} \). While of course in our case we start with a “stronger and more general foundation” (namely, our Theorem 8.2 that strengthens and generalizes Lemma 8.1, as discussed in Section 8.1), we still seek a much more careful (and generalized) analysis of the soundness of the recursive algorithms underlying \( V_{RS} \) and \( V_{VRS} \). We indeed do so and our end result is formally given in Theorem 10.1 and proved in Section 10; we now discuss at high level what the proof of this theorem involves.

The focus of our effort is improving the soundness of \( V_{RS,=} \), which is the PCPP verifier “at the bottom of the stack” (see Figure 1) responsible for testing proximity to \( RS(\mathbb{F}, L, |L|/8) \), for an affine subspace \( L \) of \( \mathbb{F} \). Indeed, \( V_{VRS} \) can be constructed based on \( V_{RS} \); \( V_{RS} \) invokes one of three PCPP verifiers, \( V_{RS,>} \), \( V_{RS,<} \), or \( V_{RS,=} \), depending on whether the fractional degree to be tested is respectively greater than, less than, or equal to 1/8; both of the PCPP verifiers \( V_{RS,>} \) and \( V_{RS,<} \) consist of few invocations of \( V_{RS,=} \). So, again, the technical heart of the construction of \( V_{RS} \) and \( V_{VRS} \) is \( V_{RS,=} \) and, while we also take the care to tighten the soundness analysis of \( V_{RS,<}, V_{RS,>} \), \( V_{RS}, V_{VRS} \), improving the soundness analysis of \( V_{RS,=} \) is where most of our effort goes. See Figure 1.

The relevant lemma for \( V_{RS,=} \) from [BSS08] (stated for affine rather than linear subspaces) is:

**Lemma 8.3** ([BSS08, Lemma 6.10]). There exists a constant \( c \geq 1 \) such that for every positive integer \( \kappa \) and every positive \( \varepsilon \) the following holds: if for a function \( p : S \rightarrow \mathbb{F}_{2^\ell} \), a string \( \pi \), an integer \( \ell \), and a \( \kappa \)-dimensional affine subspace \( L \subseteq \mathbb{F}_{2^\ell} \) it holds that

\[
\Pr \left[ V_{RS,=}^{(p, \pi)}(\mathbb{F}_{2^\ell}, L, |L|/8 - 1) = 1 \right] > 1 - \varepsilon ,
\]

then

\[
\Delta_L \left( p, RS(\mathbb{F}_{2^\ell}, L, |L|/8 - 1) \right) \leq c^{\log \kappa} \cdot \varepsilon .
\]

Recall that \( \Delta_L \) denotes the fractional Hamming distance for strings/functions defined over the set (in this case, affine subspace) \( L \). (See Definition 4.7.) Also recall that a PCPP verifier is given as input an explicit input and is granted oracle access to an implicit input and a proximity proof; in the case of \( V_{RS,=} \), the explicit input specifies the desired Reed-Solomon code and the implicit input is the function \( p \) that needs to be tested, with the aid of the proximity proof \( \pi \).

The above lemma says that the (strong) PCPP verifier \( V_{RS,=} \) has a soundness function \( s_{RS,=} \) (cf. Definition 4.15) that can be lower bounded as follows:

\[
s_{RS,=} (\delta, n) \geq \frac{\delta}{k \log \varepsilon} .
\]

We note that one cannot hope in a soundness analysis showing that \( s_{RS,=} (\delta, n) \geq \kappa^{-o(1)} \), because \( V_{RS,=} \) consists of \( O(\log \log n) = O(\log \kappa) \) recursions of a constant-soundness low-degree test (namely, the “random row or column test”), so that we indeed expect \( s_{RS,=} (\delta, n) \leq \kappa^{-O(1)} \). Therefore, the parameter of interest here is the constant \( c \), and thus our goal of obtaining a better soundness analysis for \( V_{RS,=} \) can now be technically restated as:

*find the smallest possible \( c \) such that Lemma 8.3 holds.*
Ben-Sasson and Sudan proved Lemma 8.3 for $c = (64(c_0 + 2/3))^{\log(7/6)}$ and $c_0 = 128$ (and note that, as already mentioned, the universal constant of bivariate testing $c_0$ appears as part of the soundness analysis of $V_{RS,=}$); this yields $\log c \approx 58.5$, which is clearly an impractical value. Indeed, with such an analysis, one can only show that $\hat{B}_{RS} \leq 2^{572}$. (Since values of $c$ are quite large, we shall always give its binary logarithm when computing bounds for it.)

Without modifying the original construction, we are able to improve the soundness analysis to show a constant $c$ with $\log c \approx 23.2$ as follows:

1. By using the improved universal constant of bivariate testing $c_0 = 10.24$ (by invoking our Theorem 8.2) in the old soundness analysis of $V_{RS,=}$ showing $c = (64(c_0 + 2/3))^{\log(7/6)}$ we get $\log c \approx 42.5$.

2. We perform the soundness analysis of $V_{RS,=}$ much more carefully, yielding the improved expression for $c = \left(\frac{16}{3}(1 + c_0) - 2\sqrt{16 + \frac{64}{3}(1 + c_0) + 8}\right)^{\log(7/6)}$ so that, using $c_0 = 10.24$, we get $\log c \approx 23.2$.

Unfortunately, $\log c \approx 23.2$ is still far from practicality. We attempt to go further by fine tuning details of the construction of $V_{RS,=}$, and we are able to obtain $\log c \approx 10.6$ with a slightly different construction (but the same complexity parameters — in time, proof length, and number of queries — as the original).

Even with $\log c \approx 10.6$, however, we are still far from practicality, and need to work more. And this is also where our technical approach to studying concrete efficiency of PCPP verifiers departs from “standard” approaches used to study their asymptotic efficiency. We proceed in two steps:

- We develop an analysis that lets us efficiently explore a class of $V_{RS,=}$ constructions related to the original one of Ben-Sasson and Sudan. To that end, we explicitly parametrize several quantities in the construction of $V_{RS,=}$ (namely, the fractional degree to be tested, the query complexity, and how the recursion is “balanced”) and, with the ultimate goal of deriving a precise understanding of how these parameters trade off against each other, we are able to deduce an explicit expression for the constant $c$ in terms of all of these parameters. We are then in a position to identify better tradeoffs among these parameters for any given problem size.

Concretely, see Theorem 10.3 (and Corollary 10.4) in Section 10.1 for the formal statement giving the expression for $c$ in terms of four parameters $(\eta, \kappa_0, \gamma, \mu)$, where $2^{-\eta}$ denotes the fractional degree, $2^{\kappa_0}$ the number of queries, $\gamma$ how the affine subspace $L$ is split for the recursion and $\mu$ what is the “overlap” between the two subspaces of $L$ in the recursion. In the original construction, $\eta = 3$, $\kappa_0 = 6$, $\gamma = 0$, $\mu = 2$.

(Our improved analysis also enables us to choose the larger fractional degree $2^{-\eta}$ with $\eta = 2$, whereas previously the analysis was not strong enough to show any soundness for this setting, which yields an even shorter proximity proof.)

As an example, in Table 1, we give values for $\log c$ as we change $\eta$ and $\kappa_0$ (for optimal choices of the other parameters in each case).

- We leverage our generalized soundness analysis to derive a recursive function that lets us numerically compute the “effective soundness” for any given problem size. We discover that
Table 1: Trade-offs in the choice of parameters for $V_{rs,=}$: increasing $\eta$ and $\kappa_0$ respectively increases the PCP oracle length and the query complexity; the value $\log c \approx 10.6$ for the setting $\eta = 3$ and $\kappa_0 = 6$ (in bold) corresponds to what we obtain for (a fine tuning of) the original construction, improving on the original $\log c \approx 58.5$.

8.3 Step 3: Putting Things Together

We now explain how the two steps described in the previous two subsections come together to give a proof of Theorem 2:

Proof of Theorem 2. The PCPP verifier $V_{rs,=}$ with a choice of parameters a choice of parameters $(\eta, \kappa_0, \gamma, \mu)$ tests proximity to the ensemble

$$E^{(\eta)} \defeq \{ RS(\mathbb{F}_{2^\ell}, L, d) \mid L \text{ is an affine subspace of } \mathbb{F}_{2^\ell}, d/|L| = 2^{-\eta} \}.$$  (5)

The code ensemble considered in Theorem 2 is $E_{rs} = E^{(3)}$; any code $C \in E_{rs}$ is thus fully specified by $\ell$ and $L$. Recall that

$$\hat{B}_{rs} \defeq \arg \min_{B \in \mathbb{N}} \left\{ B' \mid \forall \ [n, k, d]_{2^\ell}-\text{code } C \in E_{rs} \text{ with } k \geq B', \left( \frac{n + L(C)}{k} \right) \cdot Q(C) < \frac{1}{2} \cdot k \right\} ,$$
where $L(C)$ is the length of the PCPP proof for codewords in $C$ and $Q(C)$ is the query complexity for testing proximity (with soundness $1/2$) of non-codewords that are sufficiently far from $C$. By examining $V_{RS}$ (see Lemma C.1 for details), we deduce that for every $C \in E_{RS}$, letting $\kappa := \dim(L)$,

- $L(C) \leq 2^\kappa \cdot \kappa^{1+\max\{-\gamma+\mu+1,1\}}$,
- $Q(C) \leq 2^{\kappa_0} \cdot \kappa^{\log c(\eta,\kappa_0,\gamma,\mu)}$.\(^{16}\)

Thus, recalling that $n = |L| = 2^\kappa$, if

$$(1 + \kappa^{1+\max\{-\gamma+\mu+1,1\}}) \cdot 2^{\kappa_0} \cdot \kappa^{\log c(\eta,\kappa_0,\gamma,\mu)} < \frac{1}{2} \cdot 2^\kappa$$

then

$$\left(\frac{n + L(C)}{k}\right) \cdot Q(C) < \frac{1}{2} \cdot k .$$

Then, Theorem 10.3 tells us a bound on $\log c(\eta,\kappa_0,\gamma,\mu)$, so that we can now compute a bound on $\hat{B}_{RS}$ by using Equation 6. In fact, we can numerically compute $L(C)$ exactly and, moreover, the proof of Theorem 10.3 enables us to numerically evaluate a bound on $\log c(\eta,\kappa_0,\gamma,\mu)$ (as discussed in Section 10.1.4); we do so in our computations to obtain an even better bound on $\hat{B}_{RS}$.

For example, using the parameters $(\eta,\kappa_0,\gamma,\mu) = (3,14,1,2)$, we get $\hat{B}_{RS} \leq 2^{35}$, as claimed. (In contrast, using the original parameters $(\eta,\kappa_0,\gamma,\mu) = (3,6,0,2)$ and the bound $\log c \approx 58.5$ obtained in [BSS08], we only get $\hat{B}_{RS} \leq 2^{572}$.\(^{\square}\)

\(^{16}\)Note that the number of queries $2^{\kappa_0}$ has been multiplied by $\kappa^{\log c(\eta,\kappa_0,\gamma,\mu)}$ to take into account the fact that the verifier that has been amplified to achieve soundness $1/2$; see Remark 10.2.
9 Improved Universal Constant of Bivariate Testing

After recalling some basic lemmas about polynomials from [Spi95] (Section 9.1), we prove Theorem 8.2 in two steps (respectively in Section 9.2 and Section 9.3); as an example, we then show how to obtain the improved universal constant of bivariate testing $c_0 = 10.24$ (Section 9.4).

9.1 Some Basic Lemmas

Let us recall some basic lemmas needed for the proof of the theorem.

Lemma 9.1 ([Spi95, Proposition 4.2.9]). Let $A = \{\alpha_1, \ldots, \alpha_m\} \subseteq \mathbb{F}$, $B = \{\beta_1, \ldots, \beta_n\} \subseteq \mathbb{F}$, $d < m$, and $e < n$. Let $f : A \times B \rightarrow \mathbb{F}$ be a function such that for every $\alpha \in A$ it holds that $f(\alpha, y)$ agrees with some polynomial over $\mathbb{F}$ of degree $d$ and for every $\beta \in B$ it holds that $f(x, \beta)$ agrees with some polynomial over $\mathbb{F}$ of degree $e$. Then there exists a polynomial $P(x, y)$ over $\mathbb{F}$ of degree $(d, e)$ such that $f$ agrees with $P$ everywhere on $A \times B$.

Proof sketch. By “stringing together” $e + 1$ low-degree row polynomials via Lagrange interpolation in one variable. □

Lemma 9.2 ([Spi95, Lemma 4.2.13]). Let $\mathbb{F}$ be a field, $A = \{\alpha_1, \ldots, \alpha_m\} \subseteq \mathbb{F}$, and $B = \{\beta_1, \ldots, \beta_n\} \subseteq \mathbb{F}$. Let $S \subseteq A \times B$ be a set of size at most $\delta^2 mn$. Then there exists a non-zero polynomial $E(x, y)$ over $\mathbb{F}$ of degree $(\delta m, \delta n)$ such that $E(\alpha, \beta) = 0$ for all $(\alpha, \beta) \in S$.

Proof sketch. The “evaluation map” is a linear operator; in this case, the domain is a vector space of dimension $(\lfloor \delta m \rfloor + 1)(\lfloor \delta n \rfloor + 1)$ and the range is a vector space of dimension $\delta^2 mn$; hence the kernel contains more than one element and, in particular, a non-zero solution. □

Lemma 9.3 ([Spi95, Lemma 4.2.14]). Let $\mathbb{F}$ be a field, $A = \{\alpha_1, \ldots, \alpha_m\} \subseteq \mathbb{F}$, and $B = \{\beta_1, \ldots, \beta_n\} \subseteq \mathbb{F}$. Let $E(x, y), P(x, y), R(x, y), C(x, y)$ be polynomials over $\mathbb{F}$ of respective degrees $(\delta m, \delta n), (d + \delta m, e + \delta n), (d, n), (m, e)$ such that for every $(\alpha, \beta) \in A \times B$ it holds that $P(\alpha, \beta) = R(\alpha, \beta)E(\alpha, \beta) = C(\alpha, \beta)E(\alpha, \beta)$. If $|A| > d + \delta m$ then for all $\alpha \in A$ it holds that $E(\alpha, y)$ divides $P(\alpha, y)$. If $|B| > e + \delta n$ then for all $\beta \in B$ it holds that $E(x, \beta)$ divides $P(x, \beta)$.

Proof sketch. For any $\alpha \in A$, $P(\alpha, y)$ and $R(\alpha, y)E(\alpha, y)$ agree on $|B| > e + \delta n$ points, and thus they are equal as formal polynomials. Similarly for the other coordinate. □

Lemma 9.4 ([Spi95, Lemma 4.2.18]). Let $\mathbb{F}$ be a field, $A = \{\alpha_1, \ldots, \alpha_m\} \subseteq \mathbb{F}$, and $B = \{\beta_1, \ldots, \beta_n\} \subseteq \mathbb{F}$. Let $E(x, y)$ and $P(x, y)$ be polynomials over $\mathbb{F}$ of respective degrees $(\delta m, \delta n)$ and $(\delta' m + \delta m, \varepsilon' n + \varepsilon n)$. Suppose that for every $\alpha \in A$ and $\beta \in B$ it holds that $E(\alpha, y)$ divides $P(\alpha, y)$ and $E(x, \beta)$ divides $P(x, \beta)$. If $1 > \delta' + \varepsilon' + \delta + \varepsilon$ then $E(x, y)$ divides $P(x, y)$.

Proof sketch. The proof is non-trivial; it uses resultants and their derivatives. (An alternate proof using dimensions of vector spaces can be found in [Sze05].) □

9.2 The PS Bivariate Testing Theorem

We begin by stating and proving the Polishchuk Spielman Bivariate Testing Theorem with our slightly improved parameters:
Theorem 9.5. Let $\mathbb{F}$ be a field, $A = \{\alpha_1, \ldots, \alpha_m\} \subseteq \mathbb{F}$, and $B = \{\beta_1, \ldots, \beta_n\} \subseteq \mathbb{F}$. Let $R(x, y)$ be a polynomial over $\mathbb{F}$ of degree $(d, n)$ and let $C(x, y)$ be a polynomial over $\mathbb{F}$ of degree $(m, e)$. Suppose that

$$\Pr_{(\alpha, \beta)\in A \times B} [R(\alpha, \beta) \neq C(\alpha, \beta)] < \delta^2 \text{ and } 1 > \frac{d}{m} + \frac{e}{n} + 2\delta.$$ 

Then there exists a polynomial $Q$ over $\mathbb{F}$ of degree $(d, e)$ such that

$$\Pr_{(\alpha, \beta)\in A \times B} [R(\alpha, \beta) \neq Q(\alpha, \beta) \text{ or } C(\alpha, \beta) \neq Q(\alpha, \beta)] < 2\delta^2.$$ 

The improvement is in that we relax the original requirement $1 > 2 \left(\frac{d}{m} + \frac{e}{n} + \delta\right)$ to the new requirement $1 > \frac{d}{m} + \frac{e}{n} + 2\delta$, by simply being more careful in the original proof and combining it with another proof of the theorem appearing in [Sze05, Theorem 5.30].

Proof of Theorem 9.5. Let $S = \{(\alpha, \beta) \in A \times B \text{ s.t. } R(\alpha, \beta) \neq C(\alpha, \beta)\}$; by assumption, $|S| < \delta^2 mn$. By Lemma 9.2, there exists a (non-zero) polynomial $E(x, y)$ over $\mathbb{F}$ of degree $(\delta m, \delta n)$ such that $E(S) = \{0\}$. Note that $R(x, y)E(x, y)$ is a polynomial of degree $(d + \delta m, n + \delta n)$ and $C(x, y)E(x, y)$ is a polynomial of degree $(m + \delta m, e + \delta n)$.

By Lemma 9.1, there exists a polynomial $P(x, y)$ over $\mathbb{F}$ of degree $(d + \delta m, e + \delta n)$ such that for every $(\alpha, \beta) \in A \times B$ it holds that $P(\alpha, \beta) = R(\alpha, \beta)E(\alpha, \beta) = C(\alpha, \beta)E(\alpha, \beta)$.

By hypothesis we know that $m > d + \delta m$ and $n > e + \delta n$; therefore by Lemma 9.3 we deduce that for all $\alpha \in A$ it holds that $E(\alpha, y)$ divides $P(\alpha, y)$ and for all $\beta \in B$ it holds that $E(x, \beta)$ divides $P(x, \beta)$.

By hypothesis we know that $1 > \delta' + \varepsilon' + \delta + \varepsilon$, where we define $\delta' := \frac{d}{m}$, $\varepsilon' := \frac{e}{n}$, $\varepsilon := \delta$; therefore by Lemma 9.4 we deduce that $E(x, y)$ divides $P(x, y)$.

So define $Q(x, y) := P(x, y)/E(x, y)$, and note that $Q(x, y)$ is of degree $(d, e)$ and for every $(\alpha, \beta) \in A \times B$ it holds that $Q(\alpha, \beta)E(\alpha, \beta) = R(\alpha, \beta)E(\alpha, \beta) = C(\alpha, \beta)E(\alpha, \beta)$.

Let $T = \{(\alpha, \beta) \in A \times B \text{ s.t. } R(\alpha, \beta) = C(\alpha, \beta) \neq Q(\alpha, \beta)\}$. Note that

$$\{ (\alpha, \beta) \in A \times B \text{ s.t. } R(\alpha, \beta) \neq Q(\alpha, \beta) \text{ or } C(\alpha, \beta) \neq Q(\alpha, \beta) \} \subseteq T \cup S.$$ 

We now argue that $|T| \leq \delta^2 mn$. (And doing so will complete the proof, since $|S| < \delta^2 mn$ by assumption.)

Indeed, assume by way of contradiction that $|T| > \delta^2 mn$. Then either $A_1 := \{\alpha \in A \text{ s.t. } \exists \beta \in B \text{ with } (\alpha, \beta) \in T\}$ has size greater than $\delta m$ or $B_1 := \{\beta \in B \text{ s.t. } \exists \alpha \in A \text{ with } (\alpha, \beta) \in T\}$ has size greater than $\delta n$.

Suppose that $|A_1| > \delta m$. Fix any $\alpha \in A_1$. Note that $R(\alpha, y)$ and $Q(\alpha, y)$ are distinct polynomials. However, we know that $Q(\alpha, y)E(\alpha, y)$ and $R(\alpha, y)E(\alpha, y)$ agree everywhere on $B$. Since $|B| = n > e + \delta n \geq \deg_y Q + \deg_y E$, we deduce that $E(\alpha, y)$ is identically zero, and thus $(x - \alpha)$ is a factor of $E$. We conclude that $\prod_{\alpha \in A_1} (x - \alpha)$ divides $E$, but this is a contradiction because $|A_1| > \delta m$ and $\deg_x E \leq \delta m$.

Suppose that $|B_1| > \delta n$ instead. We can then argue in the same way. Namely, fix any $\beta \in B_1$. Note that $R(x, \beta)$ and $Q(x, \beta)$ are distinct polynomials. However, we know that $Q(x, \beta)E(x, \beta)$ and $R(x, \beta)E(x, \beta)$ agree everywhere on $A$. Since $|A| = m > d + \delta m \geq \deg_x Q + \deg_x E$, we deduce that $E(x, \beta)$ is identically zero, and thus $(y - \beta)$ is a factor of $E$. We conclude that $\prod_{\beta \in B_1} (y - \beta)$ divides $E$, but this is a contradiction because $|B_1| > \delta n$ and $\deg_y E \leq \delta n$. \qed

43
9.2.1 Barriers to further improvements

It is not clear whether one can relax further the requirement that \( 1 > \frac{d}{m} + \frac{e}{n} + 2\delta \) in Theorem 9.5. So let us briefly discuss how this requirement arises in the proof of Theorem 9.5. There are three main places:

(i) Having found \( E \) such that \( P(\alpha, \beta) = R(\alpha, \beta) \) for every \((\alpha, \beta) \in A \times B\), we use the fact that \( 1 > \frac{d}{m} + \delta \) and \( 1 > \frac{e}{n} + \delta \) to deduce (via Lemma 9.3) that for every \( \alpha \in A \) and \( \beta \in B \) it holds that \( E(\alpha, \beta) \) divides \( P(\alpha, \beta) \) and \( E(x, \beta) \) divides \( P(x, \beta) \).

(ii) Then, we use the fact that \( 1 > \frac{d}{m} + \frac{e}{n} + \frac{2}{m} \) to deduce (via Lemma 9.4) that \( E(x, y) \) divides \( P(x, y) \).

(iii) Later in the proof, we use (again) the fact that \( 1 > \frac{d}{m} + \frac{e}{n} + \delta \) to deduce (via Lemma 9.3) that \( |T| \leq \delta^2 mn \).

The requirement in (ii) is the more stringent one and, in our view, is the one that one should be able to relax further. We now briefly describe prospects of improving it.

A limit to Lemma 9.4. In the proof of Theorem 9.5 we are given the set of “errors” \( S \) (i.e., those places where the row polynomial \( R \) differs from the column polynomial \( C \)), and need to find an error-locator polynomial \( E \) vanishing on \( S \) for which we can show that \( E \) divides the induced \( P \). Roughly, the way this is currently done is to ensure that \( E \) has low-degree in both variables (namely, \( \delta m \) and \( \delta n \) respectively, enough to ensure that one always exists) and then invoking the “Bézout-type” argument of Lemma 9.4.

It is easy to note, however, that the requirement \( 1 > \delta' + \varepsilon' + \delta + \varepsilon \) in Lemma 9.4 (which translates into the requirement \( 1 > \frac{d}{m} + \frac{e}{n} + 2\delta \) of (ii)) cannot be improved beyond \( 2 > \delta' + \varepsilon' + \delta + \varepsilon \) (which would translate into the relaxed requirement \( 2 > \frac{d}{m} + \frac{e}{n} + 2\delta \)). Indeed, consider the choice of polynomials

\[
P(x, y) = \left( \prod_{i=1}^{m} (x - \alpha_i) \right) \left( \prod_{i=1}^{n} (y - \beta_i) \right) \quad \text{and} \quad E(x, y) = x - y ;
\]

even though \( E \) does divide \( P \) in every row and column (as \( P \) is zero), it is not the case that \( E \) divides \( P \). (In this example, we would have \( \delta = \frac{1}{m} \), \( \varepsilon = \frac{1}{n} \), \( \delta' = \frac{m-1}{m} \), and \( \varepsilon' = \frac{n-1}{n} \), in which case \( \delta' + \varepsilon' + \delta + \varepsilon = 2 \).

Nonetheless, this observation is not discouraging at all, as improving Theorem 9.5 to a requirement such as \( 2 > \frac{d}{m} + \frac{e}{n} + 2\delta \) would be great, and in fact seems a reasonable goal.

9.3 The Universal Constant for Bivariate Testing

We re-prove Lemma 8.1 via a case analysis that is a slight refinement of the case analysis originally used in [BSS08, proof of Lemma 6.12]. Specifically, the two analyses differ in that we split the two cases according to a bound on the sum of \( \delta_A^{(d, \ast)}(g) \) and \( \delta_B^{(\ast, e)}(g) \), while [BSS08] split according to a bound on each of the two quantities; this improves the constant by a factor of two.

In fact, we state and prove the (improved) lemma of Ben-Sasson and Sudan in a more general form, by using the generic fractional degrees \( \frac{d}{m} \) and \( \frac{e}{n} \) (as opposed to \( \frac{1}{4} \) and \( \frac{1}{8} \) as in the original lemma).
Define \( \Phi(\delta, d, m, e, n) \) to be a “\( \delta \)-monotone” predicate denoting whether Theorem 9.5 holds for the proximity parameter \( \delta > 0 \) and fractional degrees \( \frac{d}{m} \) and \( \frac{e}{n} \).\(^{17}\) (For example, we can take \( \frac{7}{d} \geq \frac{d}{m} + \frac{e}{n} + 2\delta \) as the predicate \( \Phi(\delta, d, m, e, n) \).

**Lemma 9.6.** Let \( \mathbb{F} \) be a field. Let \( d, m, e, n \in \mathbb{N} \) be such that \( \Phi(\delta, d, m, e, n) = 1 \) for some positive \( \delta \). Then we can take

\[
c_0 := \max \left\{ 3, \inf \left\{ \delta^{-2} : \delta > 0 \text{ and } \Phi(\delta, d, m, e, n) = 1 \right\} \right\}
\]

in Lemma 8.1. That is, for every two finite subsets \( A \) and \( B \) of \( \mathbb{F} \) of respective sizes \( m \) and \( n \) and every function \( g: A \times B \rightarrow \mathbb{F} \), it is the case that

\[
\delta_{A \times B}(g) \leq c_0 \cdot \left( \delta_{A \times B}(g) + \delta_{A \times B}^{(s,e)}(g) \right).
\]

**Proof of Lemma 9.6.** We distinguish between two cases:

**Case 1.** Suppose that \( \delta_{A \times B}^{(d,e)}(g) + \delta_{A \times B}^{(s,e)}(g) < 1/c_0 \). Fix any \( \varepsilon > 0 \) with \( 0 < \varepsilon < 1/c_0 - \delta_{A \times B}^{(d,e)}(g) - \delta_{A \times B}^{(s,e)}(g) \). Let \( R(x, y) \) be the polynomial corresponding to a codeword in \( \text{RM}(\mathbb{F}, A \times B, (d, |B| - 1)) \) closest to \( g \); note that \( \Delta_{A \times B}(g, R) = \delta_{A \times B}^{(d,e)}(g) \). By the triangle inequality,

\[
\delta_{A \times B}^{(d,e)}(g) = \Delta_{A \times B}(g, \text{RM}(\mathbb{F}, A \times B, (d, e))) \\
\leq \Delta_{A \times B}(g, R) + \Delta_{A \times B}(R, \text{RM}(\mathbb{F}, A \times B, (d, e))) \\
= \delta_{A \times B}^{(d,e)}(g) + \Delta_{A \times B}(R, \text{RM}(\mathbb{F}, A \times B, (d, e))) .
\]

Let \( C(x, y) \) be the polynomial corresponding to a codeword in \( \text{RM}(\mathbb{F}, A \times B, (|A| - 1, e)) \) closest to \( g \); note that \( \Delta_{A \times B}(g, C) = \delta_{A \times B}^{(s,e)}(g) \). By the triangle inequality,

\[
\delta_{A \times B}^{(d,e)}(g) = \Delta_{A \times B}(g, \text{RM}(\mathbb{F}, A \times B, (d, e))) \\
\leq \Delta_{A \times B}(g, C) + \Delta_{A \times B}(C, \text{RM}(\mathbb{F}, A \times B, (d, e))) \\
= \delta_{A \times B}^{(s,e)}(g) + \Delta_{A \times B}(C, \text{RM}(\mathbb{F}, A \times B, (d, e))) .
\]

For the choice \( \delta_c = \sqrt{\delta_{A \times B}^{(d,e)}(g) + \delta_{A \times B}^{(s,e)}(g) + \varepsilon} < 1/c_0 \), note that the following two conditions hold:

\[
\Pr_{(\alpha, \beta) \in A \times B} \left[ R(\alpha, \beta) \neq C(\alpha, \beta) \right] = \Delta_{A \times B}(R, C) \\
\leq \Delta_{A \times B}(R, g) + \Delta_{A \times B}(g, C) \\
= \delta_{A \times B}^{(d,e)}(g) + \delta_{A \times B}^{(s,e)}(g) \\
< \delta_c^2
\]

and

\[
\Phi(\delta_c, d, m, n, e) = 1 .
\]

\(^{17}\)By “\( \delta \)-monotone” we mean that if \( \Phi(\delta, d, m, e, n) = 1 \) for some \( \delta \) then for any \( \delta' \in (0, \delta) \) we also have \( \Phi(\delta', d, m, e, n) = 1 \).
(Indeed, letting $\tilde{\delta} := \sup\{\delta : \delta > 0$ and $\Phi(\delta, d, m, e, n) = 1\}$, we see that $c_0 = \max\{3, 1/\tilde{\delta}^2\}$. Since $\delta_\varepsilon < \frac{1}{\sqrt{c_0}}$, we deduce that $\delta_\varepsilon < \frac{1}{\sqrt{\max\{3, 1/\tilde{\delta}^2\}}} \leq \frac{1}{\sqrt{1/\tilde{\delta}^2}} = \tilde{\delta}$, so that $\Phi(\delta_\varepsilon, d, m, n, e) = 1$ as we just claimed.)

Hence, invoking Theorem 9.5 with the $F$, $A$, $B$, $d$, $m$, $e$, $n$, $R$, and $C$ of this proof, and using $\delta = \delta_\varepsilon$, we deduce that $\Delta_{A \times B}(R, \text{RM}(F, A \times B, (d, e))) < 2\delta_\varepsilon^2$ and $\Delta_{A \times B}(C, \text{RM}(F, A \times B, (d, e))) < 2\delta_\varepsilon^2$; combining with the two upperbounds on $\delta_{A \times B}(g)$ derived earlier, we obtain

$$
\delta_{A \times B}(g) = \frac{\delta_{(d,e)}(g)}{2} + \frac{\delta_{A \times B}(g)}{2} \leq \frac{\delta_{(d,e)}(g)}{2} + \frac{\delta_{(d,e)}(g)}{2} + 2\delta_\varepsilon^2 = \frac{5\delta_{(d,e)}(g)}{2} + \frac{5\delta_{(d,e)}(g)}{2} + \varepsilon .
$$

Choosing $\varepsilon$ small enough, we get $\delta_{A \times B}(g) \leq 3 \cdot \left(\frac{\delta_{(d,e)}(g)}{2} + \frac{\delta_{(d,e)}(g)}{2}\right)$.

Case 2. Suppose that $\delta_{A \times B}(g) + \delta_{A \times B}(g) \geq 1/c_0$. Then the upperbound on $\delta_{A \times B}(g)$ holds trivially:

$$
\delta_{A \times B}(g) \leq 1 = c_0 \cdot \frac{1}{c_0} \leq c_0 \cdot \left(\frac{\delta_{(d,e)}(g)}{2} + \frac{\delta_{(d,e)}(g)}{2}\right) .
$$

In either case, we have shown the desired upper bound on $\delta_{A \times B}(g)$. \qed

### 9.4 Putting Things Together

Combining Theorem 9.5 and Lemma 9.6, we obtain Theorem 8.2.

For example, by using the best predicate $\Phi(\delta, d, m, e, n)$ we could prove (namely, $1 > \frac{d}{m} + \frac{e}{n} + 2\delta$ as the predicate $\Phi(\delta, d, m, e, n)$ from Theorem 9.5) and by setting $\frac{d}{m} = 1/4$ and $\frac{e}{n} = 1/8$ as in Lemma 8.1, we recover the (improved) constant $c_0 = 10.24$, as opposed to the previous value $c_0 = 128$.  

46
10 Improved Soundness for $V_{RS}$ and $V_{VRS}$

We prove a much tighter soundness analysis for the verifiers $V_{RS}$ and $V_{VRS}$ (cf. Algorithm 13 and Algorithm 12), which respectively are supposed to test proximity to RS and VRS over affine subspaces of finite field extensions of $F_2$. We show the following theorem:

**Theorem 10.1.** The (strong) PCPP verifiers $V_{RS}$ and $V_{VRS}$ have respective soundness functions

$$s_{RS}(\delta, n) \geq \frac{1}{1 + 2^{2n+1+\eta\log c}} \delta$$

$$s_{VRS}(\delta, n) \geq \frac{1}{2 + 2^{2n+1+\eta\log c}} \delta,$$

where $n = 2^\kappa$, $(\eta, \kappa_0, \gamma, \mu)$ are any integers satisfying

$$\min\left\{ \left\lfloor \frac{\kappa_0 + 1}{2} \right\rfloor - \gamma, \left\lceil \frac{\kappa_0 + 1}{2} \right\rceil + \gamma \right\} \geq 1$$

$$\max\left\{ \left\lfloor \frac{\kappa_0 + 1}{2} \right\rfloor - \gamma + \mu + 1, \left\lceil \frac{\kappa_0 + 1}{2} \right\rceil + \gamma \right\} < \kappa_0 + 1$$

and

$$c \overset{\text{def}}{=} \left( a - \sqrt{b(b + 4a) - b} \right) \min\{ \log\left( \frac{\log c}{(\kappa_0 + 1)/2 - 1 + \mu + \gamma} \right), \log\left( \frac{\log c}{(\kappa_0 + 1)/2 + 1} \right) \},$$

where

$$a \overset{\text{def}}{=} \frac{2^{\eta+1}(1 + c_0)}{2^{\eta-1} - 1},$$

$$b \overset{\text{def}}{=} 2^{\eta+1},$$

$$c_0 \overset{\text{def}}{=} \frac{4}{\left( \frac{1}{2^{\eta}} - \frac{1}{2^{\gamma}} \right)^2}.$$  

(Alternatively, for any given problem size $n = 2^\kappa$, one can use the method discussed in Section 10.1.4 to compute an “effective” $c$, which is usually much better than the theoretical expression given above.)

We perform our improved soundness analyses “from bottom to top” (see the lowermost five “verifier boxes” in Figure 1 for dependencies):

- in Section 10.1 we analyze the soundness of $V_{RS,=}$;
- in Section 10.2 we analyze the soundness of $V_{RS,<}$;
- in Section 10.3 we analyze the soundness of $V_{RS,>}$;
- in Section 10.4 we analyze the soundness of $V_{RS}$; and
- in Section 10.5 we analyze the soundness of $V_{RS}$.

**Remark 10.2** (From Strong PCPPs to “Weak” PCPPs). The PCPPs obtained in Theorem 10.1 are of the “strong” kind, i.e., follow Definition 4.15, instead of the weaker Definition 4.14.

In general, (naive) sequential repetition of a strong PCPP verifier with soundness function $s: \{0, 1\} \times \mathbb{N} \to \{0, 1\}$ to obtain a (“weak”) PCPP verifier with proximity parameter $\delta \in [0, 1]$ and soundness parameter $s' \in [0, 1]$ requires a number of repetitions $m_{s,\delta,s'}(n)$ such that

$$m_{s,\delta,s'}(n) = \left\lceil \frac{\log(1 - s')}{\log(1 - s(\delta, n))} \right\rceil,$$  

where $n$ is the length of the explicit input.
We are not interested in randomness-efficient sequential repetition (cf. [BSS08, Proposition 2.9]), because we are not concerned with saving randomness and naive sequential repetition is much more efficient computationally. Hence, we shall always perform naive sequential repetition for the purpose of soundness amplification.

In particular, for the specific case \( s' \defeq \frac{1}{2} \), we get that

\[
m_{s_0,\delta_0}(n) = \left\lceil \frac{-1}{\log \left( 1 - s_0(n) \right)} \right\rceil \leq \left\lceil \frac{1}{s_0(n)} \right\rceil .
\]

Thus, we can bound the number of repetitions of \( V_{\text{RS}} \) and \( V_{\text{VRS}} \) required for soundness \( s'_{\text{RS}} := s'_{\text{VRS}} := \frac{1}{2} \) and proximity parameters \( \delta_{\text{RS}} \) and \( \delta_{\text{VRS}} \) respectively as follows:

\[
\left\lceil \frac{\log (1 - s'_{\text{RS}})}{\log (1 - s_{\text{RS}}(\delta_{\text{RS}}, 2^\kappa))} \right\rceil \leq \left\lceil \frac{1}{s_{\text{RS}}(\delta_{\text{RS}}, 2^\kappa)} \right\rceil \leq \left\lceil \frac{1}{\delta_{\text{RS}} \left( 1 + \frac{2^{\eta+1} + \kappa \log \epsilon}{1 - 2^{-\eta}} \right)} \right\rceil
\]

and

\[
\left\lceil \frac{\log (1 - s'_{\text{VRS}})}{\log (1 - s_{\text{VRS}}(\delta_{\text{VRS}}, 2^\kappa))} \right\rceil \leq \left\lceil \frac{1}{s_{\text{VRS}}(\delta_{\text{VRS}}, 2^\kappa)} \right\rceil \leq \left\lceil \frac{1}{\delta_{\text{VRS}} \left( 1 + \frac{2^{\eta+1} + \kappa \log \epsilon}{1 - 2^{-\eta}} \right)} \right\rceil .
\]

In general, we denote by \( V_{\text{RS}} \) and \( V_{\text{VRS}} \) the amplified versions of \( V_{\text{RS}} \) and \( V_{\text{VRS}} \): they each take the same inputs as the non-amplified version, as well as the two additional inputs respectively specifying the target soundness and proximity parameter. See Algorithm 11 and Algorithm 10 for more details.

### 10.1 Soundness Analysis of \( V_{\text{RS},=\kappa} \)

The “engine” for testing proximity to RS is the verifier \( V_{\text{RS},=\kappa} \), whose job is to test proximity to \( \text{RS}(\mathbb{F}_2^\ell, L, |L|/8 - 1) \) where \( L \) is some \( \kappa \)-dimensional affine subspace of \( \mathbb{F}_{2^\ell} \).

As mentioned in the introduction, we have generalized the construction of \( V_{\text{RS},=\kappa} \) (its code is given in Algorithm 16) and we shall provide a much tighter soundness analysis, provided by the following theorem:

**Theorem 10.3.** Consider a construction of \( V_{\text{RS},=\kappa} \) parametrized by integers \( (\eta, \kappa_0, \gamma, \mu) \) as described above, with

\[
\min \left\{ \left\lceil \frac{\kappa_0 + 1}{2} \right\rceil - \gamma, \left\lceil \frac{\kappa_0 + 1}{2} \right\rceil + \gamma \right\} \geq 1 \quad \text{and} \quad \mu + 1 \geq \eta \geq \max\{2, \mu + 1\} .
\]

There exists a constant \( c \geq 1 \) such that for every positive integer \( \kappa \) and every positive \( \epsilon \) the following holds: if for a function \( p: L \to \mathbb{F}_{2^\ell} \), a string \( \pi \), an integer \( \ell \), and a \( \kappa \)-dimensional affine subspace \( L \subseteq \mathbb{F}_{2^\ell} \) it holds that

\[
\text{Pr}\left[ V_{\text{RS},=\kappa}^{(p, \pi)}(\mathbb{F}_{2^\ell}, L, |L|/2^\eta - 1) = 1 \right] > 1 - \epsilon
\]

then

\[
\Delta_L\left(p, \text{RS}(\mathbb{F}_{2^\ell}, L, |L|/2^\eta - 1) \right) \leq c^{\log \kappa} \cdot \epsilon .
\]
In fact, we can take $c$ to be the following value:

$$c \overset{\text{def}}{=} \left( a - \sqrt{b(b + 4a) - b} \right) \frac{1}{2} \min \{ \log \left( \frac{\kappa_0 + 1}{(\kappa_0 + 1)^2 - 1 + 1} \right), \log \left( \frac{\kappa_0 + 1}{(\kappa_0 + 1)^2} \right) \},$$

where

$$\begin{aligned}
a &\overset{\text{def}}{=} 2^{\eta_1 + 1} (1 + c_0) > 0 \\
b &\overset{\text{def}}{=} 2^{\mu + 2} > 0 \\
c_0 &\overset{\text{def}}{=} \frac{4}{(1 - \frac{1}{2^2})}.
\end{aligned}$$

(In particular, for any given $\eta \geq 2$ and $\kappa_0 \geq 1$, we are forced to choose $\mu = \eta - 1$ and we can optimally choose $\gamma$ as the integer, among those allowed by Equation 8, minimizing the exponent in the above expression.)

The above theorem simply says that $V_{RS,=}$ is a (strong) PCPP verifier with inverse-polylogarithmic soundness:

**Corollary 10.4.** The (strong) PCPP verifier $V_{RS,=}$ has soundness function

$$s_{RS,=}(\delta, n) \geq \frac{\delta}{\kappa \log c}.$$

We first prove some lemmas (Section 10.1.1) and introduce basic notation and facts for the proof (Section 10.1.2), then provide the theoretical analysis of the soundness function (Section 10.1.3), and after that we explain how our analysis lets us numerically compute a better lower bound on the soundness for any given dimension (Section 10.1.4).

Throughout, for a subset $W$ of $\mathbb{F}_2^\ell \times \mathbb{F}_2^\ell$, we call the $\beta$-row of $W$ the set $W_\beta = \{ \alpha : (\alpha, \beta) \in W \}$ and the $\alpha$-column of $W$ the set $W_\alpha = \{ \beta : (\alpha, \beta) \in W \}$; given a function $g : W \rightarrow \mathbb{F}_2^\ell \times \mathbb{F}_2^\ell$ the restriction of $g$ to the $\beta$-row of $W$ is denoted $g|_\beta$ and the restriction of $g$ to the $\alpha$-column of $W$ is denoted by $g|_\alpha$.

### 10.1.1 Some lemmas

We begin by proving some lemmas needed for the soundness analysis of $V_{RS,=}$ in Section 10.1.3.

The first two lemmas state that the relative distance of a function to bivariate polynomials whose degree is restricted in only one of the two variables can be understood as the “average” of the distance of the restriction of the function to a column to univariate low-degree polynomials:

**Lemma 10.5.** Let $\mathbb{F}$ be a finite field, $A$ and $B$ subsets of $\mathbb{F}$, $g : A \times B \rightarrow \mathbb{F}$ a function, and $d$ a positive integer. Then:

$$\delta^{(d, \star)}_{A \times B}(g) = \mathbb{E}_{b \in B} \left[ \delta_{A}^{(d)}(g|_b) \right],$$

where $g|_b : A \rightarrow \mathbb{F}$ denotes the restriction of $g$ to the $b$-th row.

**Lemma 10.6.** Let $\mathbb{F}$ be a finite field, $A$ and $B$ subsets of $\mathbb{F}$, $g : A \times B \rightarrow \mathbb{F}$ a function, and $e$ a positive integer. Then:

$$\delta^{(\star, e)}_{A \times B}(g) = \mathbb{E}_{a \in A} \left[ \delta_{B}^{(e)}(g|_a) \right],$$

where $g|_a : B \rightarrow \mathbb{F}$ denotes the restriction of $g$ to the $a$-th column.

The proofs of these lemmas were left implicit in [BSS08]. For completeness, we give the proof of Lemma 10.5; an analogous argument can be carried out to prove the (symmetric) Lemma 10.6.

49
Proof of Lemma 10.5. Re-writing the left-hand side of Equation 11:
\[
\delta^{(d,+)}_{A \times B}(g) = \min_{Q \in \mathbb{F}[x,y]} \Delta_{A \times B}(g,Q)
\]
\[
= \min_{Q \in \mathbb{F}[x,y]} \left\{ (a, b) \in A \times B : g(a, b) \neq Q(a, b) \right\} \frac{|A| \cdot |B|}{|\mathbb{F}|^d}
\]
\[
= \frac{1}{|A| \cdot |B|} \sum_{b \in B} \min_{Q \in \mathbb{F}[x]} \Delta_A(g|_b^+, Q)
\]
\[
= \frac{1}{|A| \cdot |B|} \sum_{b \in B} \min_{Q \in \mathbb{F}[x]} \left\{ a \in A : g(a, b) \neq Q(a) \right\} \frac{|A|}{|\mathbb{F}|^d}
\]  \hspace{1cm} (13)

Re-writing the right-hand side of Equation 11:
\[
\mathbf{E}_{b \in B} \left[ \delta_A^{(d)}(g|_b^+) \right] = \frac{1}{|B|} \cdot \sum_{b \in B} \delta_A^{(d)}(g|_b^+)
\]
\[
= \frac{1}{|B|} \cdot \sum_{b \in B} \min_{Q \in \mathbb{F}[x]} \Delta_A(g|_b^+, Q)
\]
\[
= \frac{1}{|B|} \cdot \sum_{b \in B} \min_{Q \in \mathbb{F}[x]} \left\{ a \in A : g(a, b) \neq Q(a) \right\} \frac{|A|}{|\mathbb{F}|^d}
\]  \hspace{1cm} (14)

Let \( P \) be a bivariate polynomial over \( \mathbb{F} \) (with degree in \( x \) at most \( d \)) that minimizes the summation in Equation 13; hence,
\[
\delta^{(d,+)}_{A \times B}(g) = \frac{1}{|A| \cdot |B|} \cdot \sum_{b \in B} \left\{ a \in A : g(a, b) \neq P(a, b) \right\}.
\]

For every \( b \in B \): define the univariate polynomial \( P_b \) over \( \mathbb{F} \) by \( P_b(x) := P(x, b) \); note that the degree of \( P_b \) is at most \( d \); observe that
\[
\left\{ a \in A : g(a, b) \neq P(a, b) \right\} \geq \min_{Q \in \mathbb{F}[x]} \left\{ a \in A : g(a, b) \neq Q(a) \right\}.
\]

Thus,
\[
\delta^{(d,+)}_{A \times B}(g) = \frac{1}{|A| \cdot |B|} \cdot \sum_{b \in B} \left\{ a \in A : g(a, b) \neq P(a, b) \right\}
\]
\[
\geq \frac{1}{|A| \cdot |B|} \cdot \sum_{b \in B} \min_{Q \in \mathbb{F}[x]} \left\{ a \in A : g(a, b) \neq Q(a) \right\}
\]
\[
= \mathbf{E}_{b \in B} \left[ \delta_A^{(d)}(g|_b^+) \right].
\]  \hspace{1cm} (15)
We now prove the other inequality, necessary to deduce equality. For every \( b \in B \): let \( R_b \) be the univariate polynomial over \( \mathbb{F} \) (with degree in \( x \) at most \( d \)) that minimizes the \( b \)-summand in the summation of Equation 14, so that

\[
\mathbb{E}_{b \in B} \left[ \delta_A^{(d)} (g|_b^+) \right] = \frac{1}{|A| \cdot |B|} \cdot \sum_{b \in B} \left| \left\{ a \in A : g(a,b) \neq R_b(a) \right\} \right|.
\]

Letting, for every \( b \in B \), \( S_b \) denote any univariate polynomial over \( \mathbb{F} \) such that \( S_b(b) = 1 \) and \( S_b(B - \{ b \}) = \{0\} \), define the bivariate polynomial \( P \) over \( \mathbb{F} \) by \( P(x,y) := \sum_{b \in B} S_b(y) R_b(x) \); note that the degree of \( P \) in \( x \) is at most \( d \). Observe that

\[
\sum_{b \in B} \left| \left\{ a \in A : g(a,b) \neq R_b(a) \right\} \right| = \sum_{b \in B} \left| \left\{ a \in A : g(a,b) \neq S_b(b) R_b(a) \right\} \right|
\]

\[
= \sum_{b \in B} \left| \left\{ a \in A : g(a,b) \neq P(a,b) \right\} \right|
\]

\[
\geq \min_{Q \in \mathbb{F}[x,y]} \sum_{\text{deg}_x(Q) \leq d} \sum_{b \in B} \left| \left\{ a \in A : g(a,b) \neq Q(a,b) \right\} \right|.
\]

Thus,

\[
\mathbb{E}_{b \in B} \left[ \delta_A^{(d)} (g|_b^+) \right] = \frac{1}{|A| \cdot |B|} \cdot \sum_{b \in B} \left| \left\{ a \in A : g(a,b) \neq R_b(a) \right\} \right|
\]

\[
\geq \frac{1}{|A| \cdot |B|} \cdot \min_{Q \in \mathbb{F}[x,y]} \sum_{\text{deg}_x(Q) \leq d} \sum_{b \in B} \left| \left\{ a \in A : g(a,b) \neq Q(a,b) \right\} \right|
\]

\[
= \delta_A^{(d+)^+}(g).
\]

From Equation 15 and Equation 16, we deduce Equation 11, as desired. \( \square \)

The next lemma highlights some properties of vanishing polynomials for affine subspaces, generalizing those presented in [BSS08, Proposition 6.4].

**Lemma 10.7.** Let \( L \) be an affine subspace of \( \mathbb{F}_2^\kappa \) with a basis \( \mathcal{B}_L = (a_1, \ldots, a_\kappa) \) and offset \( \mathcal{O}_L \), and let \( j \in \{1, \ldots, \kappa - 1\} \). Define:

\[
L_0^* := \text{span}(a_1, \ldots, a_j) \quad \text{and} \quad L_1^* := \text{span}(a_{j+1}, \ldots, a_\kappa)
\]

\[
L_0 := L_0^* + \mathcal{O}_L \quad \text{and} \quad L_1 := L_1^* + \mathcal{O}_L.
\]

Let \( Z_{L_0} \) be the vanishing polynomial of \( L_0 \), i.e., \( Z_{L_0}(x) := \prod_{\alpha \in L_0} (x - \alpha) \). Then:

- The polynomial \( Z_{L_0} \) is an \( \mathbb{F}_2 \)-affine map and its kernel is \( L_0 \).
- \( Z_{L_0}(L) = Z_{L_0}(L_1) \) and \( Z_{L_0}(L_1) \) is a linear subspace of dimension \( \text{dim}(L_1) \).
- \( Z_{L_0} \) is a one-to-one map from \( L_1 \) to \( Z_{L_0}(L_1) \).
- \( Z_{L_0} \) is a \( |L_0| \)-to-one map from \( L \) to \( Z_{L_0}(L_1) \); moreover the affine subspace \( L_0 + \beta + \mathcal{O}_L \) is mapped to \( Z_{L_0}(\beta) \) for each \( \beta \in L_1 \).
\textbf{Proof.} The above properties follow from observations on the form of $Z_{L_0}$; see Algorithm 21.

More precisely, $Z_{L_0}(x) = Z_{L_0}^*(x) + Z_{L_0}^{\circ}(\mathcal{O}_L)$, where $Z_{L_0}^*$ is the vanishing polynomial of $L_0^*$; moreover, $Z_{L_0}^*(x) = \sum_{j=0}^l \beta_j x_j^2$ for some coefficients $\beta_1, \ldots, \beta_j$, so that $Z_{L_0}^*$ is an $\mathbb{F}_2$-linear map with kernel equal to $L_0^*$. We deduce that $Z_{L_0}$ is an $\mathbb{F}_2$-affine map and its kernel is $L_0$.

Next, since $L = (L_0^0 + L_1^0) + \mathcal{O}_L$, we know that

$$Z_{L_0}(L) = Z_{L_0}((L_0^0 + L_1^0) + \mathcal{O}_L) = Z_{L_0}((L_0^0 + L_1^0) + \mathcal{O}_L) + Z_{L_0}^*(\mathcal{O}_L) = Z_{L_0}^*(L_1^0) + \mathcal{O}_L;$$

moreover, the above derivation tells us that $Z_{L_0}(L_1) = Z_{L_0}^*(L_1^0)$, which is a linear subspace of dimension $\dim(L_1^0) = \dim(L_1)$.

Next, it is easy to show that $Z_{L_0}^*$ is a one-to-one map from $L_1^0$ to $Z_{L_0}^*(L_1^0)$ and that $Z_{L_0}^*$ is a $|L_0^0|$-to-one map from $L_0^0 + L_1^0$ to $Z_{L_0}^*(L_1^0)$. From these facts we immediately deduce that $Z_{L_0}$ is a one-to-one map from $L_1$ to $Z_{L_0}(L_1)$ and $Z_{L_0}$ is a $|L_0|$-to-one map from $L$ to $Z_{L_0}(L_1)$.

Finally, for $\beta \in L_1$,

$$Z_{L_0}(L_0 + \beta + \mathcal{O}_L) = Z_{L_0}((L_0^0 + \mathcal{O}_L) + \beta + \mathcal{O}_L) = Z_{L_0}((L_0^0 + \mathcal{O}_L) + \beta + \mathcal{O}_L) + Z_{L_0}^*(\mathcal{O}_L) = Z_{L_0}(\beta) + Z_{L_0}^*(\mathcal{O}_L) = Z_{L_0}(\beta),$$

as desired. \qed

\subsection{Basic notation}

We introduce basic notation and facts needed for the soundness analysis of $V_{\text{rs,=}P}$ in Section 10.1.3.

Let $(a_1, \ldots, a_\kappa)$ be any basis for the given affine subspace $L$; let $\mathcal{O}$ be the offset of $L$. Define the affine subspaces $L_0, L_0', L_1, L_\beta$ of $L$ as follows:

$$L_0 := \text{span}(a_1, \ldots, a_{\lfloor \kappa / 2 \rfloor} - \gamma) + \mathcal{O}$$

so that $\dim(L_0) = \lfloor \kappa / 2 \rfloor - \gamma$;

$$L_0' := \text{span}(a_1, \ldots, a_{\lfloor \kappa / 2 \rfloor} - \gamma + \mu) + \mathcal{O}$$

so that $\dim(L_0') = \lfloor \kappa / 2 \rfloor - \gamma + \mu$;

$$\forall \beta \in L_1, L_\beta := \begin{cases} \text{span}(a_1, \ldots, a_{\lfloor \kappa / 2 \rfloor} - \gamma + \mu, a_{\lfloor \kappa / 2 \rfloor} - \gamma + \mu + 1) + \mathcal{O} & \beta \in L_0' \\ \text{span}(a_1, \ldots, a_{\lfloor \kappa / 2 \rfloor} - \gamma + \mu, \beta + \mathcal{O}) + \mathcal{O} & \beta \notin L_0' \end{cases}$$

so that $\dim(L_\beta) = \lfloor \kappa / 2 \rfloor - \gamma + \mu + 1$;

$$L_1 := \text{span}(a_{\lfloor \kappa / 2 \rfloor} - \gamma + 1, \ldots, a_\kappa) + \mathcal{O}$$

so that $\dim(L_1) = \lfloor \kappa / 2 \rfloor + \gamma$.

Note that $L_0, L_0', L_1, L_\beta$ are defined similarly to [BSS08, Definition 6.4], with the exception of the additional parameters $\gamma$ and $\mu$ that we introduce to control their sizes and the fact that we work with affine (rather than linear) subspaces. Essentially, $\gamma$ lets us choose a different decomposition of $L$ into $L_0$ and $L_1$ (originally, $\gamma = 0$), and $\mu$ lets us control how much bigger is $L_0'$ as compared to $L_0$ (originally, $\mu = 2$). Also, Equation 8 guarantees that $L_0, L_0', L_1, L_\beta$ all have positive dimension and all have dimension less than $\kappa$ (that is, at most $\kappa$ to make sense, and in fact strictly less than it so we make “progress”).
Define the linearized polynomial $Z_{L_0}$ to be the vanishing polynomial of $L_0$; more precisely, since $Z_{L_0}$ is a vanishing polynomial of an affine (rather than linear) subspace, the polynomial $Z_{L_0}$ is an affine (rather than linear) map. (See Lemma 10.7.)

Define the two disjoint subsets $T$ and $S$ of $\mathbb{F}_{2^\ell} \times \mathbb{F}_{2^\ell}$ as follows:

$$T := \bigcup_{\beta \in L_1} \left( (L_0 + \beta + \mathcal{O}_L) \times \{Z_{L_0}(\beta)\} \right) \quad \text{and} \quad S := \left( \bigcup_{\beta \in L_1} (L_\beta \times \{Z_{L_0}(\beta)\}) \right) - T.$$ 

We now introduce the “format” of a proximity proof $\pi$ expected by $V_{\text{rs,=}}(\mathbb{F}_{2^\ell}, L, |L|/2^\eta - 1)$; this format is defined by induction on $\kappa$ and generalizes [BSS08, Definition 6.4]. If $\kappa \leq \kappa_0$, then $\pi$ is empty. Otherwise, $\pi = (f, \Pi)$ where $f$ is a partial bivariate function over partial domain $S$ and $\Pi$ is a sequence of proximity proofs for Reed-Solomon codes over smaller affine subspaces. Concretely, $\Pi$ has a subproof $\pi^\downarrow_{\beta'}$ for a Reed-Solomon codeword over $L_{\beta'}$ for each $\beta' = Z_{L_0}(\beta) \in Z_{L_0}(L_1)$ and has a subproof $\pi^\uparrow_{\beta}$ for a Reed-Solomon codeword over $Z_{L_0}(L_1)$ for each $\alpha \in L_0$; thus, overall, $\Pi = \{\pi^\downarrow_{\beta'} : \beta' \in Z_{L_0}(L_1)\} \cup \{\pi^\uparrow_{\beta} : \alpha \in L_0\}$.

The next lemma extends [BSS08, Proposition 6.5] to affine subspaces, showing that $S \cup T$ can be decomposed into rows and columns that are affine subspaces of size approximately $\sqrt{|L|}$.  

**Lemma 10.8.** The set $S \cup T$ is the disjoint union of $Z_{L_0}(\beta)$-rows taken over $\beta \in L_1$; moreover, the $Z_{L_0}(\beta)$-row of $S \cup T$ is the affine subspace $L_\beta$. Similarly, for every $\alpha \in L_0$, the $\alpha$-column of $S \cup T$ is the affine (in fact, linear) subspace $Z_{L_0}(L_1)$.

**Proof.** Fix $\beta \in L_1$. By the last property of Lemma 10.7, the $Z_{L_0}(\beta)$-row of $T$ is equal to $L_0 + \beta + \mathcal{O}_L$; by the definition of $L_\beta$, $L_0 + \beta + \mathcal{O}_L \subseteq L_\beta$. We deduce that $S \cup T = \cup_{\beta \in L_1} (L_\beta \times \{Z_{L_0}(\beta)\})$.

In particular, $S \cup T$ is indeed a disjoint union of $Z_{L_0}(\beta)$-rows, where each $Z_{L_0}(\beta)$-row is equal to $L_\beta$.

Now fix $\alpha \in L_0$. For every $\beta \in L_1$, we have $L_0 \subseteq L_\beta$ and $L_\beta \times \{Z_{L_0}(\beta)\} \subseteq S$ and thus $(\alpha, Z_{L_0}(\beta)) \in S$; hence, $Z_{L_0}(\beta)$ is a subset of the $\alpha$-column. However, the only non-empty rows in $S \cup T$ are the $Z_{L_0}(\beta)$-rows, so that the $\alpha$-column of $S \cup T$ is precisely $Z_{L_0}(L_1)$. 

The proximity proof $\pi = (f, \Pi)$ as in [BSS08, Definition 6.4]. Finally, recall the definition of the two (partial) bivariate functions $\hat{p} : T \to \mathbb{F}_{2^\ell}$ and $\hat{f} : S \cup T \to \mathbb{F}_{2^\ell}$,

$$\hat{p}(\alpha, \beta') := p(\alpha) \quad \text{and} \quad \hat{f}(\alpha, \beta') := \begin{cases} f(\alpha, \beta') & \text{if } (\alpha, \beta') \in S \\ \hat{p}(\alpha, \beta') & \text{if } (\alpha, \beta') \in T \end{cases}.$$ 

Finally, given the above notation,

10.1.3 **The proof by induction**

We proceed to the proof of Theorem 10.3. Our proof follows the approach of Ben-Sasson and Sudan, which is described at high level in [BSS08, Section 6.1]; in fact, we make an explicit effort to structure our proof in the same way as was done by Ben-Sasson and Sudan, so as to benefit from their intuitive discussions (of both the algorithm and the proof), which will apply here too. For the construction of our generalized $V_{\text{rs,=} \kappa}$, see Algorithm 16; throughout, we assume basic familiarity with $V_{\text{rs,=} \kappa}$.

Without loss of generality, we assume that $\varepsilon$ is chosen so that $\varepsilon < c^{-\log \kappa}$, for otherwise there is nothing to prove because the relative distance $\Delta_L$ is at most 1.
Proof of Theorem 10.3. The proof is by induction on $\kappa$, the dimension of $L$.

The base case $\kappa \leq \kappa_0$ is immediate: by construction, $V_{\text{rs,=}L}$ accepts the implicit input $p : L \to \mathbb{F}_{2^\kappa}$ if and only if $p \in \text{RS}(\mathbb{F}_{2^\kappa}, |L|/2^n - 1)$, because $V_{\text{rs,=}L}$ queries all the values of $p$, and then verifies that the polynomial corresponding to $p$ (obtained via interpolation) has degree at most $|L|/2^n - 1$.

If instead $\kappa > \kappa_0$, assume that the lemma holds for all $\kappa' \in \mathbb{N}$ less than $\kappa$. Our goal is now to prove that the lemma holds for $\kappa$ as well. So assume that the oracle pair $(p, \pi)$ is accepted with probability greater than $1 - \varepsilon$ (Equation 9); we want to show that there exists a polynomial $P$ of degree at most $|L|/2^n - 1$ such that its evaluation over $L$ is at distance at most $D(\kappa) \cdot \varepsilon$ from $p$ (Equation 10), and want the smallest $c$ such that $D(\kappa) \leq c^{\log \kappa}$.

Recall that $V_{\text{rs,=}L}(\mathbb{F}_{2^\kappa}, |L|/2^n - 1)$ will, with equal probability, do one of the following two tests:

- row test: choose a random $\beta \in L_1$ and recurse on $V_{\text{rs,=}L}((\hat{f}|_{Z_{L_0}(\beta)}) \cdot \pi_{Z_{L_0}(\beta)}^{\perp} (\mathbb{F}_{2^\kappa}, L_\beta, |L_\beta|/2^n - 1)$, or
- column test: choose a random $\alpha \in L'_0$ and recurse on $V_{\text{rs,=}L}((\hat{f}|_{Z_{L_0}(\alpha)}) \cdot \pi_{Z_{L_0}(\alpha)}^{\perp} (\mathbb{F}_{2^\kappa}, Z_{L_0}(L_1), |Z_{L_0}(L_1)|/2^n - 1)$.

**Step 1: restricting the bivariate function $\hat{f}$ to a product set $L'_0 \times Z_{L_0}(L_1)$.** Define the following quantities:

- for every $\beta \in L_1$, $\varepsilon(\beta)$ is the probability that the inner verifier rejects $(\hat{f}|_{Z_{L_0}(\beta)}) \cdot \pi_{Z_{L_0}(\beta)}^{\perp}$;
- for every $\alpha \in L'_0$, $\varepsilon(\alpha)$ is the probability that the inner verifier rejects $(\hat{f}|_{Z_{L_0}(\alpha)}) \cdot \pi_{Z_{L_0}(\alpha)}^{\perp}$;
- $\varepsilon_{\text{row}} := \mathbf{E}_{\beta \in L_1}[\varepsilon(\beta)]$;
- $\varepsilon_{\text{col}} := \mathbf{E}_{\alpha \in L'_0}[\varepsilon(\alpha)]$;
- $d := |L_\beta|/2^n - 1$ ($d$ is the same regardless of the choice of $\beta \in L_1$);
- $e := |Z_{L_0}(L_1)|/2^n - 1$.

Note that, by construction of $V_{\text{rs,=}L}$, $\varepsilon = (\varepsilon_{\text{row}} + \varepsilon_{\text{col}})/2$ (as a random row test or a random column test is performed, with equal probability); in particular, $\varepsilon_{\text{row}}, \varepsilon_{\text{col}} \leq 2\varepsilon$. Also, by Lemma 10.8, we deduce that:

- for every $\beta \in L_1$, $(\hat{f}|_{Z_{L_0}(\beta)})$ has domain $L_\beta \times \{Z_{L_0}(\beta)\}$;
- for every $\alpha \in L'_0$, $(\hat{f}|_{Z_{L_0}(\alpha)})$ has domain $\{\alpha\} \times Z_{L_0}(L_1)$.

Using the inductive assumption, we deduce that:

$$\mathbf{E}_{\beta \in L_1} \left[ \delta_{L_\beta} (\hat{f}|_{Z_{L_0}(\beta)}) \right] \leq \mathbf{E}_{\beta \in L_1} \left[ D(\text{dim } L_\beta) \cdot \varepsilon(\beta) \right] = D(\left\lfloor \frac{n}{2} \right\rfloor - \gamma + \mu + 1) \cdot \varepsilon_{\text{row}}$$

and

$$\mathbf{E}_{\alpha \in L'_0} \left[ \delta_{Z_{L_0}(L_1)} (\hat{f}|_{Z_{L_0}(\alpha)}) \right] \leq \mathbf{E}_{\alpha \in L'_0} \left[ D(\text{dim } Z_{L_0}(L_1)) \cdot \varepsilon(\alpha) \right] = D(\left\lfloor \frac{n}{2} \right\rfloor + \gamma) \cdot \varepsilon_{\text{col}} .$$

Define the function $f' : L'_0 \times Z_{L_0}(L_1) \to \mathbb{F}_{2^\kappa}$ by $f' := (\hat{f}|_{L'_0 \times Z_{L_0}(L_1)})$, i.e., $f'$ is the restriction of $\hat{f}$ to the product set $L'_0 \times Z_{L_0}(L_1)$. Then:
For every $g = \text{bad}$ where we can now invoke Theorem 8.2 with $m + \Pr_T$. Define $\cdot$

We now bound the probability that, over a random $(\ldots) \in \mathbb{F}_2^n$, we deduce that

Using Lemma 10.6, as well as the facts that $f = f'$, and the $\ldots$ is the domain of $\hat{\alpha}$, we say that $\ldots$ is bad.

We make the following definitions:

- Let $Q(x, y)$ be the polynomial over $\mathbb{F}_2$ corresponding to a codeword in $\mathbb{R}(\ldots) \times Z_{L_0}(L_1)(d, e)$ closest to $f'$; in particular, $\delta^{(d,e)}_{L_0 \times Z_{L_0}(L_1)}(f') = \Delta_{L_0 \times Z_{L_0}(L_1)}(f', Q)$.

- For every $\beta \in L_1$, define the function $\hat{f}\big|_{Z_{L_0}(\beta)}: L_0' \to \mathbb{F}_2$ by $\hat{f}\big|_{Z_{L_0}(\beta)} := (\hat{f}\big|_{Z_{L_0}(\beta)})|_{L_0'}$ (and recall that $L_0$ is the domain of $\hat{f}\big|_{Z_{L_0}(\beta)}$, $L_0' \subseteq L_0$, and $|L_0'| = |L_0|/2$); and

- For every $\beta \in L_1$, let $Q_{\beta}(x)$ be the polynomial over $\mathbb{F}_2$ corresponding to a codeword in $\mathbb{R}(\ldots)$ closest to $\hat{f}\big|_{Z_{L_0}(\beta)}$: in particular, $\delta^{(d)}_{L_\beta}(\hat{f}\big|_{Z_{L_0}(\beta)}) = \Delta_{L_\beta}(\hat{f}\big|_{Z_{L_0}(\beta)}), Q_{\beta}(\ldots)$.

For every $\beta' \in Z_{L_0}(L_1)$, we say that $\beta'$ is good if $Q_{\beta'}(x) = Q(x, \beta')$; otherwise we say that $\beta'$ is bad. Define $T_{\text{good}} := \{(\alpha, \beta') \in T : \beta' \text{ is good}\}$.

We now bound the probability that, over a random $(\alpha, \beta') \in T$, $\hat{p}(\alpha, \beta') \neq Q(\alpha, \beta')$:

$$\Pr_{(\alpha, \beta') \in T} \left[ \hat{p}(\alpha, \beta') \neq Q(\alpha, \beta') \right] = \Pr_{(\alpha, \beta') \in T} \left[ \hat{p}(\alpha, \beta') \neq Q(\alpha, \beta') \middle| \beta' \text{ is bad} \right] \cdot \Pr_{\beta' \in Z_{L_0}(L_1)} \left[ \beta' \text{ is bad} \right]$$
$$+ \Pr_{(\alpha, \beta') \in T} \left[ \hat{p}(\alpha, \beta') \neq Q(\alpha, \beta') \middle| \beta' \text{ is good} \right] \cdot \Pr_{\beta' \in Z_{L_0}(L_1)} \left[ \beta' \text{ is good} \right]$$
\[
\leq 1 \cdot \Pr_{\beta' \in Z_{L_0}(L_1)} \left[ \beta' \text{ is bad} \right] \\
+ \Pr_{(\alpha, \beta') \in T} \left[ \hat{\beta}(\alpha, \beta') \neq Q(\alpha, \beta') \mid \beta' \text{ is good} \right] \cdot 1 \\
= \Pr_{\beta' \in Z_{L_0}(L_1)} \left[ \beta' \text{ is bad} \right] + \Pr_{(\alpha, \beta') \in T} \left[ \hat{\beta}(\alpha, \beta') \neq Q(\alpha, \beta') \mid \beta' \text{ is good} \right].
\]

(17)

We begin with a bound on the first summand Equation 17. Observe that, for every \( \beta' \in Z_{L_0}(L_1) \), if \( \beta' \) is bad, then \( Q_{\beta'}(x) \neq Q(x, \beta') \); since the degrees of both \( Q_{\beta'}(x) \) and \( Q(x, \beta') \) are at most \( \deg [L_\beta]/2^n - 1 \leq [L_0]/2^n - 1 \); then \( Q_{\beta'}(x) \) and \( Q(x, \beta') \) may agree on at most a \( 1/2^n - 1 \) fraction of the points in \( L_\beta^0 \). Therefore, by the triangle inequality,

\[
\frac{2^n - 1}{2^n - 1} \leq \Delta_{L_\beta^0}(Q_{\beta'}(x), Q(x, \beta')) \leq \Delta_{L_\beta}(Q_{\beta'}(x), \hat{f}^{\beta'}_{Z_{L_0}(\beta)}) + \Delta_{L_\beta^0}(\hat{f}^{\beta'}_{Z_{L_0}(\beta)}, Q(x, \beta')).
\]

For reasons that will become clear shortly, we try to understand the expectation, taken over a random \( \beta' \in Z_{L_0}(L_1) \), of the above two distances.

From \( L_0 \leq L_\beta \) and \( |L_0| = |L_\beta|/2 \), we obtain that

\[
\Delta_{L_\beta}(Q_{Z_{L_0}(\beta)}(x), \hat{f}^{\beta'}_{Z_{L_0}(\beta)}) \leq 2 \cdot \Delta_{L_\beta}(Q_{Z_{L_0}(\beta)}(x), \hat{f}^{\beta'}_{Z_{L_0}(\beta)}) = 2 \cdot \delta^{(d)}_{L_\beta}(\hat{f}^{\beta'}_{Z_{L_0}(\beta)}),
\]

so that

\[
\mathbf{E}_{\beta \in L_1} \left[ \Delta_{L_\beta}(Q_{Z_{L_0}(\beta)}(x), \hat{f}^{\beta'}_{Z_{L_0}(\beta)}) \right] \leq 2 \cdot \mathbf{E}_{\beta \in L_1} \left[ \delta^{(d)}_{L_\beta}(\hat{f}^{\beta'}_{Z_{L_0}(\beta)}) \right].
\]

Next, observe that, for every \( \beta' \in Z_{L_0}(L_1) \), \( \hat{f}^{\beta'}_{\beta'} = f'|^{\beta'}_{\beta'} \), because \( f' \) is simply the restriction of \( \hat{f} \) to \( L_\beta ' \times Z_{L_0}(L_1) \) and \( \hat{f}^{\beta'}_{\beta'} \) is the restriction of \( \hat{f}^{\beta'}_{\beta'} \) to \( L_\beta ' \). Hence, for every \( \beta' \in Z_{L_0}(L_1) \), it holds that \( \Delta_{L_\beta}(\hat{f}^{\beta'}_{\beta'}, Q(x, \beta')) = \Delta_{L_\beta}(f'|^{\beta'}_{\beta'}, Q(x, \beta')) \), so that

\[
\mathbf{E}_{\beta' \in Z_{L_0}(L_1)} \left[ \Delta_{L_\beta}(\hat{f}^{\beta'}_{\beta'}, Q(x, \beta')) \right] = \mathbf{E}_{\beta' \in Z_{L_0}(L_1)} \left[ \Delta_{L_\beta}(f'|^{\beta'}_{\beta'}, Q(x, \beta')) \right]
\]

\[
= \frac{1}{|Z_{L_0}(L_1)|} \sum_{\beta' \in Z_{L_0}(L_1)} \Delta_{L_\beta}(f'|^{\beta'}_{\beta'}, Q(x, \beta'))
\]

\[
= \frac{1}{|Z_{L_0}(L_1)|} \sum_{\beta' \in Z_{L_0}(L_1)} \frac{\{|\alpha \in L_\beta : Q(\alpha, \beta') \neq f'|_{\beta'}^{\beta'}(\alpha)\}|}{|L_0|}
\]

\[
= \frac{1}{|Z_{L_0}(L_1)|} \sum_{\beta' \in Z_{L_0}(L_1)} \frac{\{|\alpha \in L_\beta : Q(\alpha, \beta') \neq f'(\alpha, \beta')\}|}{|L_0|}
\]

\[
= \frac{\{(\alpha, \beta') \in L_0' \times Z_{L_0}(L_1) : Q(\alpha, \beta') \neq f'(\alpha, \beta')\}}{|L_0| \cdot |Z_{L_0}(L_1)|}
\]

\[
= \Delta_{L_\beta^0 \times Z_{L_0}(L_1)}(f', Q)
\]

\[
= \delta^{(d,e)}_{L_\beta^0 \times Z_{L_0}(L_1)}(f').
\]
Hence, we get:

\[
\Pr_{\beta \in L_1} \left[ Z_{L_0}(\beta) \text{ is bad} \right] \\
\leq \Pr_{\beta \in L_1} \left[ \Delta L_0' \left( Q_{Z_{L_0}(\beta)}(x), \hat{f} |_{Z_{L_0}(\beta)} \right) + \Delta L_0' \left( \hat{f} |_{Z_{L_0}(\beta)}, Q(x, Z_{L_0}(\beta)) \right) \right] \\
\leq \frac{2^{n-1} - 1}{2^{n-1} - 1} \cdot \mathbb{E}_{\beta \in L_1} \left[ \Delta L_0' \left( Q_{Z_{L_0}(\beta)}(x), \hat{f} |_{Z_{L_0}(\beta)} \right) + \Delta L_0' \left( \hat{f} |_{Z_{L_0}(\beta)}, Q(x, Z_{L_0}(\beta)) \right) \right] \\
\leq \frac{2^{n-1} - 1}{2^{n-1} - 1} \cdot \mathbb{E}_{\beta \in L_1} \left[ \Delta L_0' \left( Q_{Z_{L_0}(\beta)}(x), \hat{f} |_{Z_{L_0}(\beta)} \right) + \Delta L_0' \left( \hat{f} |_{Z_{L_0}(\beta)}, Q(x, Z_{L_0}(\beta)) \right) \right] \\
= \frac{2^{n-1} - 1}{2^{n-1} - 1} \cdot \mathbb{E}_{\beta \in L_1} \left[ \Delta L_0' \left( Q_{Z_{L_0}(\beta)}(x), \hat{f} |_{Z_{L_0}(\beta)} \right) + \Delta L_0' \left( \hat{f} |_{Z_{L_0}(\beta)}, Q(x, Z_{L_0}(\beta)) \right) \right]
\]

which is our upper bound for the first summand of Equation 17.

We now bound the second summand of Equation 17. First, recalling that the function \( \hat{p} : T \to \mathbb{F}_{2^t} \) agrees with \( \hat{f} : S \cup T \to \mathbb{F}_{2^t} \) on the set \( T \subseteq S \cup T \), we get:

\[
\Pr_{(\alpha, \beta') \in T} \left[ \hat{p}(\alpha, \beta') \neq Q(\alpha, \beta') \middle| \beta' \text{ is good} \right]
\]

\[
= \frac{\Pr_{(\alpha, \beta') \in T} \left[ \hat{p}(\alpha, \beta') \neq Q(\alpha, \beta') \land \beta' \text{ is good} \right]}{\Pr_{(\alpha, \beta') \in T} \left[ \beta' \text{ is good} \right]}
\]

\[
= \frac{\left\{ (\alpha, \beta') \in T : \hat{p}(\alpha, \beta') \neq Q(\alpha, \beta') \land \beta' \text{ is good} \right\}}{\left\{ (\alpha, \beta') \in T : \beta' \text{ is good} \right\}}
\]

\[
\leq \frac{\left\{ (\alpha, \beta') \in S \cup T : \hat{f}(\alpha, \beta') \neq Q(\alpha, \beta') \land \beta' \text{ is good} \right\}}{|S \cup T|}
\]

\[
= \frac{\left( \hat{f}(\alpha, \beta') \neq Q(\alpha, \beta') \right) \cdot |S \cup T|}{|T_{\text{good}}|}
\]

57
\[ \leq \min \left\{ \delta_{S \cup T}^{(d, \ast)}(\hat{f}), \delta_{S \cup T}^{(s, \ast)}(\hat{f}) \right\} \cdot \frac{|S \cup T|}{|T_{\text{good}}|} \]

\[ \leq \delta_{S \cup T}^{(d, \ast)}(\hat{f}) \cdot \frac{|S \cup T|}{|T_{\text{good}}|} \]

\[ = \mathbb{E}_{\beta \in L_1} \left[ \delta_{L, \beta}^{(d)}(\hat{f} \mid \bar{Z}_{L_0}^{(\beta)}) \right] \cdot \frac{|S \cup T|}{|T_{\text{good}}|} \]

\[ \leq D(\lceil \frac{n}{2} \rceil - \gamma + \mu + 1) \cdot \varepsilon \cdot \frac{|S \cup T|}{|T_{\text{good}}|}. \]

For every \( \beta \in L_1 \):

- by the definition of \( T \), the \( Z_{L_0}(\beta) \)-row of \( T \) is \( L_0 + \beta + O_L \), an affine shift of \( L_0 \) by \( \beta + O_L \); and

- by Lemma 10.8, the \( Z_{L_0}(\beta) \)-row of \( S \cup T \) is \( L_\beta \);

hence, from \( L_0 + \beta + O_L \subseteq L_\beta \) and \( |L_\beta| = 2^{\mu+1}|L_0| \), we deduce that \( |S \cup T|/|T_{\text{good}}| = 2^{\mu+1} \).

Therefore,

\[ \frac{|S \cup T|}{|T_{\text{good}}|} = \frac{|S \cup T|}{|T|} \cdot \frac{|T|}{|T_{\text{good}}|} = \frac{2^{\mu+1}}{1 - \Pr_{\beta' \in Z_{L_0}(L_1)} [\beta' \text{ is good}]} \cdot \frac{1}{1 - \Pr_{\beta' \in Z_{L_0}(L_1)} [\beta' \text{ is bad}]} \]

Thus, the second summand of Equation 17 can be upper bounded as follows:

\[ \Pr_{(\alpha, \beta') \in T} \left[ \hat{p}(\alpha, \beta') \neq Q(\alpha, \beta') \mid \beta' \text{ is good} \right] \leq \frac{2^{\mu+2} \cdot D(\lceil \frac{n}{2} \rceil - \gamma + \mu + 1)}{1 - \Pr_{\beta' \in Z_{L_0}(L_1)} [\beta' \text{ is bad}]} \cdot \varepsilon. \]

In conclusion, we have established that:

\[ \Pr_{(\alpha, \beta') \in T} \left[ \hat{p}(\alpha, \beta') \neq Q(\alpha, \beta') \right] \leq \Pr_{\beta' \in Z_{L_0}(L_1)} [\beta' \text{ is bad} + \frac{2^{\mu+2} \cdot D(\lceil \frac{n}{2} \rceil - \gamma + \mu + 1)}{1 - \Pr_{\beta' \in Z_{L_0}(L_1)} [\beta' \text{ is bad}]} \cdot \varepsilon, (18) \]

where

\[ \Pr_{\beta' \in Z_{L_0}(L_1)} [\beta' \text{ is bad}] \leq \frac{2^\gamma}{2^{\gamma+1}} \cdot \max\left\{ (2 + 2c_0) \cdot D(\lceil \frac{n}{2} \rceil - \gamma + \mu + 1), c_0 \cdot D(\lceil \frac{n}{2} \rceil + \gamma) \right\} \cdot \varepsilon. \] (19)

Now recall that we have assumed that \( D(\kappa) \leq c^{\log \kappa} \); we now seek the smallest \( c \) for which we can show that

\[ \Pr_{(\alpha, \beta') \in T} \left[ \hat{p}(\alpha, \beta') \neq Q(\alpha, \beta') \right] \leq c^{\log \kappa} \cdot \varepsilon. \] (20)

We observe that

\[ D(\lceil \frac{n}{2} \rceil - \gamma + \mu + 1) \leq c^{\log (\lceil \frac{n}{2} \rceil - \gamma + \mu + 1)} \leq \frac{c^{\log \kappa}}{c^{\log (\lceil \frac{n}{2} \rceil - \gamma + \mu + 1)}} \] (21)

58
and
\[
D([\frac{a}{2}] + \gamma) \leq c^{\log([\frac{a}{2}] + \gamma)} \leq \frac{c^{\log \kappa}}{c^{\log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right)}}.
\] (22)

Next, combining Equation 18 and Equation 19, by substituting the upper bounds from Equation 21 and Equation 22, and recalling that by assumption \(c \cdot \varepsilon \leq 1\), we get:
\[
\Pr_{(\alpha, \beta') \in \mathcal{T}} \left[ \tilde{p}(\alpha, \beta') \neq Q(\alpha, \beta') \right]
\leq \left( \frac{2^n}{2^{n-1} - 1} \right) \cdot \max\{ (2 + 2c_0) \cdot c^{-\log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right)} , c_0 \cdot c^{-\log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right)} \}
+ \frac{2^{n+2} \cdot c^{-\log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right)} \cdot c^{\log \kappa} \cdot \varepsilon}{1 - \frac{2^n}{2^{n-1} - 1} \cdot \max\{ (2 + 2c_0) \cdot c^{-\log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right)} , c_0 \cdot c^{-\log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right)} \}}.
\] (23)

So, noting that
\[
\max\{ (2 + 2c_0) \cdot c^{-\log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right)} , c_0 \cdot c^{-\log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right)} \}
\leq (2 + 2c_0) c^{-\min\{ \log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right) , \log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right) \}},
\]
it suffices to require that
\[
\frac{a}{x(c)} + \frac{b}{1 - \frac{a}{x(c)}} \leq 1 , \text{ where } \begin{cases} a \overset{\text{def}}{=} \frac{2^{n+1} (1 + c_0)}{2^n} & > 0 \\ b \overset{\text{def}}{=} \frac{2^{n+1} - 1}{2^n+2} & > 0 \\ x(c) \overset{\text{def}}{=} \min\{ \log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right) , \log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right) \} & > 0 \end{cases}.
\] (24)
Solving the (second-degree) inequality in \(x(c)\), we obtain that the smaller among the two solutions is
\[
a > x(c) \geq a - \frac{\sqrt{b(b + 4a)} - b}{2}.
\] (25)
Moreover, \(a - \frac{\sqrt{b(b+4a)} - b}{2} > 0\) always holds (as can be verified via the definitions of \(a\) and \(b\)). Therefore, we choose \(c\) so that \(x(c) = a - \frac{\sqrt{b(b+4a)} - b}{2}\). In other words, we choose \(c\) such that
\[
c \overset{\text{def}}{=} a - \frac{\sqrt{b(b + 4a)} - b}{2} \min\{ \log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right) , \log \left(\frac{n_0 + 1}{\lceil (r_0 + 1)/2 \rceil + \gamma} \right) \}.
\] (26)
and this choice of \(c\) will ensure that Equation 20 is satisfied.

**Step 3:** From bivariate \(\tilde{p}\) to univariate \(p\). Let \(P(x)\) be the polynomial over \(F_{2^r}\) defined by \(P(x) := Q(x, Z_{L_0}(x))\); its degree is at most \(|L|/2^n - 1\), as is possible to see by direct computation:
\[
\deg P = \deg_x(Q) + \deg(Z_{L_0}) \cdot \deg_y(Q)
\]
We argue by induction, constructing a (partial) bivariate function $f$ on the elements in $T$ so that it suffices to show that the fractional distance of $f$ from Equation 8. This constraint in fact comes from the incompleteness of the elements in $L$ and, whenever $p \in (\mathbb{F}_2^\ell, L, |L|/2^n - 1)$, we deduce that for all but at most a ($c^\log_\kappa \cdot \varepsilon$)-fraction of the elements in $L$ it holds that

$$p(\tau) = \hat{p}(\tau, Z_{L_0}(\tau)) = Q(\tau, Z_{L_0}(\tau)) = P(\tau),$$

meaning that $p$ and the evaluation of $P$ on $L$ do agree on all but at most a ($c^\log_\kappa \cdot \varepsilon$)-fraction of the elements in $L$, as desired.

**Remark 10.9 (Completeness).** In the above proof, we have not used the constraint $\mu + 1 \geq \eta$ from Equation 8. This constraint in fact comes from the *completeness* proof, which can be easily carried out in our more generic case by following the proof (in the special case) of [BSS08, Proposition 6.9]. We need to show that:

If $p : L \rightarrow \mathbb{F}_2^\ell$ is the evaluation of a polynomial $P(x)$ of degree less than $|L|/2^n$, then there exists a proximity proof $\pi$ for which $V_{\text{deg}}(\pi, L, |L|/2^n - 1)$ always accepts.

We argue by induction, constructing a (partial) bivariate function $f : S \rightarrow \mathbb{F}_2^\ell$ for which the function $\hat{f} : S \cup T \rightarrow \mathbb{F}_2^\ell$ is such that the $Z_{L_0}(\beta)$-row of $\hat{f}$ is a codeword of $\text{RS}(\mathbb{F}_2^\ell, L, |L|/2^n - 1)$ and the $\alpha$-column of $\hat{f}$ is a codeword of $\text{RS}(\mathbb{F}_2^\ell, Z_{L_0}(L_1), |Z_{L_0}(L_1)|/2^n - 1)$ for every $\beta \in L_1$ and $\alpha \in L'_0$.

Let $Q(x, y) := P(x) \mod y - Z_{L_0}(x)$, where $Z_{L_0}$ is the vanishing polynomial of $L_0$, so that:

- $P(x) = Q(x, Z_{L_0}(x))$, and
- $\deg_x(Q) < |L_0|$ and $\deg_y(Q) = \lceil \deg(P)/\deg(Z_{L_0}) \rceil < (|L|/2^n)/|L_0| = |L_1|/2^n = |Z_{L_0}(L_1)|/2^n$.

We can then set $f(\alpha, \beta') = Q(\alpha, \beta')$ for every $(\alpha, \beta') \in S$. Then, observe that $\hat{f}$ is the evaluation of $Q$ on $S \cup T$: indeed, whenever $(\alpha, \beta') \in S$ this follows from $\hat{f}(\alpha, \beta') = f(\alpha, \beta') = Q(\alpha, \beta')$; and, whenever $(\alpha, \beta') \in T$, we have that $\beta' = Z_{L_0}(\alpha)$, so that

$$\hat{p}(\alpha, \beta') = \hat{p}(\alpha, Z_{L_0}(\alpha)) = p(\alpha) = P(\alpha) = Q(\alpha, Z_{L_0}(\alpha)) = Q(\alpha, \beta').$$

Therefore:

$$\leq d + |L_0| \cdot e$$

$$= \left(\frac{|L_0|}{2^n} - 1\right) + |L_0| \cdot \left(\frac{|Z_{L_0}(L_1)|}{2^n} - 1\right)$$

$$= \left(\frac{|L_0|}{2^n} - 1\right) + \left(\frac{|L_1|}{2^n} - 1\right)$$

$$= \left(2^{\dim(L_0)} - \eta - 1\right) + 2^{\dim(L_0)} \cdot \left(2^{\dim(L_1)} - \eta - 1\right)$$

$$= \left(2^{\|/2} - \gamma + \mu + 1 - \eta - 1\right) + 2^{\|/2} - \gamma \cdot \left(2^{\|/2} + \gamma - \eta - 1\right)$$

$$= (2^{\kappa - \eta} - 1) + (2^{\|/2} - \gamma + \mu + 1 - \eta - 1 - 1)$$

$$= (2^{\kappa - \eta} - 1) + (2^{\|/2} - \gamma + \mu + 1 - \eta - 1 - 1)$$

$$\leq (2^{\kappa - \eta} - 1) + 0$$

$$= \frac{|L|}{2^n} - 1.$$

Thus, the evaluation of $P$ on $L$ is a codeword in $\text{RS}(\mathbb{F}_2^\ell, L, |L|/2^n - 1)$, and, to finish the proof, it suffices to show that the fractional distance of $p$ to the evaluation of $P$ on $L$ is at most $c^\log_\kappa \cdot \varepsilon$. 

And, indeed, from the upperbound provided by Equation 20 and from the definition of $T$ as the set $T = \{(\tau, Z_{L_0}(\tau)) : \tau \in L\}$, we deduce that for all but at most a ($c^\log_\kappa \cdot \varepsilon$)-fraction of the elements in $L$ it holds that

$$p(\tau) = \hat{p}(\tau, Z_{L_0}(\tau)) = Q(\tau, Z_{L_0}(\tau)) = P(\tau),$$

meaning that $p$ and the evaluation of $P$ on $L$ do agree on all but at most a ($c^\log_\kappa \cdot \varepsilon$)-fraction of the elements in $L$, as desired. 

\[\square\]
• for each $\beta \in L_1$, the $Z_{L_0}(\beta)$-row of $S \cup T$ is $L_\beta$ and, by construction, the restriction of $\hat{f}$ to $L_\beta$ is the evaluation of $Q(x, Z_{L_0}(\beta))$ over $L_\beta$; hence, because $\mu + 1 \geq \eta$,

$$\deg(Q(x, Z_{L_0}(\beta))) \leq \deg_x(Q) < |L_0| = \frac{|L_\beta|}{2\mu+1} \leq \frac{|L_\beta|}{2\eta} .$$

• for each $\alpha \in L_0$, the $\alpha$-column of $\hat{f}$ is $Z_{L_0}(L_1)$ and, by construction, the restriction of $\hat{f}$ to $Z_{L_0}(L_1)$ is the evaluation of $Q(\alpha, y)$ on $Z_{L_0}(L_1)$; hence,

$$\deg(Q(\alpha, y)) \leq \deg_y(Q) < \frac{|Z_{L_0}(L_1)|}{2\eta} .$$

This completes the proof of completeness.

10.1.4 Soundness for concrete dimensions

While the soundness analysis of Section 10.1.3 provides vast improvements in the asymptotic constant $c$ in the exponent of $\kappa$ in the soundness lower bound $s_{RS,=}(\delta, n) \geq \frac{\delta}{\kappa \log c}$, we seek more. This time, however, we shall turn to a concrete analysis, and only worry for soundness of all practical problem sizes — our asymptotic analysis was set up in a way that it could easily also yield a concrete soundness analysis.

Our starting point is Equation 18 and Equation 19 that we can summarize as the following requirement on $D(\kappa)$:

$$D(\kappa) = \begin{cases} 1 & \text{if } \kappa \leq \kappa_0 \\ \frac{2^n}{2\eta+1} \cdot \max\{(2 + 2c_0) \cdot D\left(\left\lceil \frac{\kappa}{2} \right\rceil - \gamma + \mu + 1\right), c_0 \cdot D\left(\left\lceil \frac{\kappa}{2} \right\rceil + \gamma\right)\} & \text{if } \kappa > \kappa_0 \end{cases} .$$

(27)

The above recursive function lets us, for any given dimension $\kappa$, compute the “effective” $\log c$ for $\kappa$ as follows:

$$\log c(\kappa) \overset{def}{=} \frac{\log D(\kappa)}{\log \kappa} .$$

(28)

The behavior of $\log c(\kappa)$ is pleasantly well below the asymptotic bound for all practical sizes (e.g., for $\kappa$ up to 100 or 200).

10.2 Soundness Analysis of $V_{RS,<}$

The (strong) PCPP verifier $V_{RS,<}$ (cf. Algorithm 15) tests proximity to $RS(\mathbb{F}, S, d)$ for $d < |S|/2^n - 1$; it is constructed using the (strong) PCPP verifier $V_{RS,=}$.

The soundness of $V_{RS,<}$ was already analyzed (in the special case $\eta = 3$) in [BSS08, Proposition 6.13]. We give here a tighter analysis of the soundness of $V_{RS,<}$, where, compared to [BSS08, Proposition 6.13], (beyond keeping track of the parameter $\eta$) we improve on the reduction from the soundness of $V_{RS,=}$ by almost a factor of 2 in the distance argument of the soundness function.

**Lemma 10.10.** If $V_{RS,=}$ has monotone soundness function $s_{RS,=}(\delta, n)$, then $V_{RS,<}$ has soundness function

$$s_{RS,<}(\delta, n) \geq \frac{2^n - 1}{2\eta+1} s_{RS,=}(\delta, n) .$$

61
Proof. Fix an explicit input \((F, S, d)\) and an implicit input \(p: S \to \mathbb{F}\) to \(V_{RS,<}\) such that \(d < d_{k,n}\), where \(d_{k,n} := |S|/2^\eta - 1\). Also let \(\pi = (\pi_1, \pi_2)\) be any proximity proof given to \(V_{RS,<}\). Define \(\delta := \Delta_S(p, RS(F, S, d))\) and assume that \(\delta > 0\).

Consider a parameter \(\mu \in (0, 1)\) that we will optimize later. We distinguish between two cases:

- **Case 1:** \(\Delta_S(p, RS(F, S, d_{k,n})) > \mu \delta\).
  
  Then, by the soundness of \(V_{RS,=}\) and the monotonicity of \(s_{RS,=}\), the first subtest of \(V_{RS,<}^{(p,\pi)}\), which is \(V_{RS,<}^{(p,\pi)}(F, S)\), rejects with probability at least \(s_{RS,=}(\mu \delta, n)\).

- **Case 2:** \(\Delta_S(p, RS(F, S, d_{k,n})) \leq \mu \delta\).
  
  Then, \(p\) is both \(\delta\)-far from \(RS(F, S, d)\) and \(\mu \delta\)-close to \(RS(F, S, d_{k,n})\). Therefore, there exists a polynomial \(P: \mathbb{F} \to \mathbb{F}\) such that \(d < \deg(P) \leq d_{k,n}\) and whose evaluation table over \(S\) is \(\mu \delta\)-close to \(p\). Define the polynomial \(Q: \mathbb{F} \to \mathbb{F}\) by \(Q(x) := x^{d_{k,n} - d} \cdot \mu\), let \(q\) be its evaluation table over \(S\), and define the function \(p': S \to \mathbb{F}\) by \(p' := q \cdot P\). Then, \(p'\) is \(\mu \delta\)-close to the evaluation over \(S\) of the polynomial \(P': \mathbb{F} \to \mathbb{F}\) defined by \(P'(x) := Q(x) \cdot P(x)\); note that \(\deg(P') \leq (d_{k,n} - d) + d = d_{k,n}\). Since \(d_{k,n} = |S|/2^\eta - 1\), the evaluation table of \(P'\) over \(S\) is \(2^{\eta - 2^\eta} = \frac{2^{\eta - 1}}{2^\eta}\)-far from \(RS(F, S, d_{k,n})\), so that \(p'\) is \(\left(\frac{2^{\eta - 1}}{2^\eta} - \mu \delta\right)\)-far from \(RS(F, S, d_{k,n})\).

Hence, by the soundness of \(V_{RS,=}\), the second subtest of \(V_{RS,<}^{(p,\pi)}\), which is \(V_{RS,<}^{(p',\pi_2)}(F, S)\), rejects with probability at least \(s_{RS,<}(\frac{2^{\eta - 1}}{2^\eta} - \mu \delta, n)\), which, by the monotonicity of \(s_{RS,=}\), is at least \(s_{RS,<}(\frac{2^{\eta - 1}}{2^\eta} - \mu \delta, n)\).

Letting \(\mu = \frac{2^{\eta - 1}}{2^\eta} + 1\) (the solution to \(\mu = \frac{2^{\eta - 1}}{2^\eta} - \mu\)) completes the proof of the lemma. \(\Box\)

**Corollary 10.11.** The (strong) PCPP verifier \(V_{RS,<}\) has soundness function

\[
s_{RS,<}(\delta, n) \geq \frac{2^\eta - 1}{2^\eta + 1} \cdot \frac{\delta}{c}.
\]

**Proof.** Immediate from Corollary 10.4 and Lemma 10.10. \(\Box\)

### 10.3 Soundness Analysis of \(V_{RS,>}\)

The (strong) PCPP verifier \(V_{RS,>}\) (cf. Algorithm 14) tests proximity to \(RS(F, S, d)\) for \(d > |S|/2^\eta - 1\); it is constructed using the (strong) PCPP verifiers \(V_{RS,=}\) and \(V_{RS,<}\).

The soundness of \(V_{RS,>}\) was already analyzed (in the special case \(\eta = 3\)) in [BSS08, Proposition 6.13]. We give here a tighter analysis of the soundness of \(V_{RS,>}\), where, compared to [BSS08, Proposition 6.13], (beyond keeping track of the parameter \(\eta\)) we improve on the reduction from the soundness of \(V_{RS,=}\) and \(V_{RS,<}\) by optimizing over how the case analysis is split.

**Lemma 10.12.** If \(V_{RS,=}\) and \(V_{RS,<}\) have monotone soundness functions \(s_{RS,=}(\delta, n)\) and \(s_{RS,<}(\delta, n)\), then, for any \(\tau \in (0, 1)\), \(V_{RS,>}\) has soundness function

\[
s_{RS,>}(\delta, n) \geq \min \left\{ (1 - \tau) \delta, s_{RS,=} \left( \frac{\tau}{2^\eta} \delta, n \right), s_{RS,<} \left( \frac{\tau}{2^\eta} \delta, n \right) \right\}.
\]

**Proof.** Fix an explicit input \((F, S, d)\) and an implicit input \(p: S \to \mathbb{F}\) to \(V_{RS,>}\) such that \(d > d_{k,n}\), where \(d_{k,n} := |S|/2^\eta - 1\). Without loss of generality, \(d < |S| = 2^\eta(d_{k,n} + 1)\), otherwise \(p\) is always in \(RS(F, S, d)\). Also let \(\pi = ((p_0, \pi_0), \ldots, (p_{2^\eta - 1}, \pi_{2^\eta - 1}))\) be any proximity proof given to \(V_{RS,>}\). Define \(\delta := \Delta_S(p, RS(F, S, d))\) and assume that \(\delta > 0\).
Define the function \( q: S \to \mathbb{F} \) by \( q(\alpha) = \sum_{i=0}^{2^n-1} \alpha^{i(d_{\kappa, \eta}+1)} p_i(\alpha) \) for all \( \alpha \in S \). For any \( \tau \in (0, 1) \), we distinguish between two cases:

- **Case 1:** \( \Delta_S(p, q) > (1 - \tau)\delta \).
  
  Then, by construction, the second subtest of \( V_{RS,>} \) rejects with probability at least \((1 - \tau)\delta\).

- **Case 2:** \( \Delta_S(p, q) \leq (1 - \tau)\delta \).
  
  Then, there exists some \( p_i \) such that \( p_i \) is \( \frac{\tau\delta}{2^n} \)-far from \( \text{RS}(\mathbb{F}, S, d_i) \). If \( d_i = d_{\kappa, \eta} \), then the first subtest of \( V_{RS,>}^{(p, \pi)} \), which includes the test \( V_{RS,=}^{(p, \pi)}(\mathbb{F}, S) \), rejects with probability at least \( s_{RS,=}(\frac{\tau\delta}{2^n}, n) \); if instead \( d_i < d_{\kappa, \eta} \), then the first subtest of \( V_{RS,>}^{(p, \pi)} \), which includes the test \( V_{RS,>}^{(p, \pi)}(\mathbb{F}, S, d_i) \), rejects with probability at least \( s_{RS,<}(\frac{\tau\delta}{2^n}, n) \).

Thus the soundness is given by the minimum among the three possible rejection probabilities.

\[ \square \]

**Corollary 10.13.** The (strong) PCPP verifier \( V_{RS,>} \) has soundness function

\[
s_{RS,>}(\delta, n) \geq \frac{1}{1 + \frac{2^{n+1}+\log e}{1-2^{-n}}} \delta.
\]

**Proof.** From Lemma 10.10, we know that \( s_{RS,<}(\delta, n) \leq s_{RS,=}(\delta, n) \), so, from Lemma 10.12, we know that \( s_{RS,>}(\delta, n) \geq \min\{(1 - \tau)\delta, s_{RS,<}(\frac{\tau\delta}{2^n}, n)\} \). Moreover, from Corollary 10.11, we know that \( s_{RS,<}(\frac{\tau\delta}{2^n}, n) \geq \frac{\tau\delta}{2^n} \frac{2^n-1}{\log e} \delta \).

Therefore, we need to (optimally) choose \( \tau \in (0, 1) \) to ensure that \((1 - \tau)\delta = \frac{\tau\delta}{2^n} \frac{2^n-1}{\log e} \delta \); the equality is achieved for \( \tau = \frac{1}{1+a} \), where \( a = \frac{1-2^{-n}}{2^n+1} \) which, once plugged back in \((1 - \tau)\delta \) gives the claimed lower bound for \( s_{RS,>}(\delta, n) \).

\[ \square \]

### 10.4 Soundness Analysis of \( V_{RS} \)

The (strong) PCPP verifier \( V_{RS} \) (cf. Algorithm 13) tests proximity to \( \text{RS}(\mathbb{F}, S, d) \) with no restrictions on \( d \); it is constructed using the (strong) PCPP verifiers \( V_{RS,=}, V_{RS,<}, \) and \( V_{RS,>} \).

The soundness analysis of \( V_{RS} \) (implicit in [BSS08]) is trivial:

**Lemma 10.14.** If \( V_{RS,=}, V_{RS,<}, \) and \( V_{RS,>} \) have respective soundness functions \( s_{RS,=}, s_{RS,<}, \) and \( s_{RS,>} \), then \( V_{RS} \) has soundness function

\[
s_{RS}(\delta, n) \geq \min\left\{ s_{RS,=}(\delta, n), s_{RS,<}(\delta, n), s_{RS,>}(\delta, n) \right\}.
\]

**Proof.** The verifier \( V_{RS} \) simply calls \( V_{RS,<}, V_{RS,=}, \) or \( V_{RS,>} \), depending on whether the input degree \( d \) is less than, equal to, or greater than \( d_{\kappa, \eta} := |S|/2^n - 1 \). Hence, the soundness function of \( V_{RS} \) is no worse than the minimum among the soundness functions of \( V_{RS,<}, V_{RS,=}, \) and \( V_{RS,>} \).

\[ \square \]

**Corollary 10.15.** The (strong) PCPP verifier \( V_{RS} \) has soundness function

\[
s_{RS}(\delta, n) \geq \frac{1}{1 + \frac{2^{n+1}+\log e}{1-2^{-n}}} \delta.
\]

**Proof.** From Lemma 10.10 and Lemma 10.12 we know that \( s_{RS,<}(\delta, n) \leq s_{RS,=}(\delta, n) \) and \( s_{RS,>}(\delta, n) \leq s_{RS,<}(\delta, n) \) respectively. Hence, from Lemma 10.14, we know that \( s_{RS}(\delta, n) \geq s_{RS,>}(\delta, n) \), which can be lower bounded by Corollary 10.13, yielding the claimed lower bound. (And thus we have established the first lower bound from Theorem 10.1.)

\[ \square \]
10.5 Soundness Analysis of $V_{VRS}$

The (strong) PCPP verifier $V_{VRS}$ (cf. Algorithm 12) tests proximity to $VRS(\mathbb{F}, S, H, d)$ with no restrictions on $d$; it is constructed using the (strong) PCPP verifier $V_{RS}$.

The soundness of $V_{VRS}$ was already analyzed (in the special case $\eta = 3$) in [BSS08, Lemma 3.12]. We give here a tighter analysis of the soundness of the soundness of $V_{VRS}$, where, compared to [BSS08, Lemma 3.12], (beyond keeping track of the parameter $\eta$) we improve on the reduction from the soundness of $V_{RS}$ by optimizing over how the case analysis is split.

**Lemma 10.16.** If $V_{RS}$ has monotone soundness function $s_{RS}(\delta, n)$, then, for any $\tau \in (0, 1)$, $V_{VRS}$ has soundness function

$$s_{VRS}(\delta, n) \geq \min\{s_{RS}(\tau\delta, n), (1 - \tau)\delta\}.$$  

**Proof.** Fix an explicit input $(\mathbb{F}, S, H, d)$ and an implicit input $p : S \rightarrow \mathbb{F}$ to $V_{VRS}$. Also let $\pi = (\tilde{p}, \tilde{\pi})$ be any proximity proof given to $V_{VRS}$. Define $\delta := \Delta_S(p, VRS(\mathbb{F}, S, H, d))$ and assume that $\delta > 0$.

We distinguish between two cases:

- **Case 1:** $\Delta_S(\tilde{p}, RS(\mathbb{F}, S, d - |H|)) > \tau\delta$.

  Then, by the soundness of $V_{RS}$ and the monotonicity of $s_{RS}$, the first subtest of $V_{VRS}^{(p, \pi)}$, which is $V_{RS}^{(\tilde{p}, \tilde{\pi})}(\mathbb{F}, S, d - |H|)$, rejects with probability at least $s_{RS}(\delta, n)$.

- **Case 2:** $\Delta_S(\tilde{p}, RS(\mathbb{F}, S, d - |H|)) \leq \tau\delta$.

  Then, there exists a polynomial $Q : \mathbb{F} \rightarrow \mathbb{F}$ of degree at most $d - |H|$ such that its evaluation table $q$ over $S$ is $\tau\delta$-close to $\tilde{p}$. Let $Z_H : \mathbb{F} \rightarrow \mathbb{F}$ be the vanishing polynomial for the subspace $H$ (see Algorithm 21), and let $z_H$ be its evaluation over $S$. Observe that the function $z_H \cdot q$ is a codeword in $VRS(\mathbb{F}, S, H, d)$; moreover, $\Delta_S(z_H \cdot \tilde{p}, z_H \cdot q) \leq \tau\delta$. Therefore,

$$\delta = \Delta_S(p, VRS(\mathbb{F}, S, H, d)) \leq \Delta_S(p, z_H \cdot \tilde{p}) + \Delta_S(z_H \cdot \tilde{p}, VRS(\mathbb{F}, S, H, d)) = \Delta_S(p, z_H \cdot \tilde{p}) + \Delta_S(z_H \cdot \tilde{p}, z_H \cdot q) \leq \Delta_S(p, z_H \cdot \tilde{p}) + \tau\delta,$$

so that $p$ is at least $(1 - \tau)\delta$-far from $z_H \cdot \tilde{p}$, and thus the second subtest of $V_{VRS}^{(p, \pi)}$ rejects with probability at least $(1 - \tau)\delta$.

Thus the soundness is given by the minimum among the two possible rejection probabilities. □

**Corollary 10.17.** The (strong) PCPP verifier $V_{VRS}$ has soundness function

$$s_{VRS}(\delta, n) \geq \frac{1}{2 + \frac{2^{\eta + 1} + \log c}{1 - 2^{-\eta}}} \delta.$$  

**Proof.** From Lemma 10.16, know that $s_{VRS}(\delta, n) \geq \min\{s_{RS}(\tau\delta, n), (1 - \tau)\delta\}$. Moreover, from Corollary 10.15, we know that $s_{RS}(\delta, n) \geq \frac{1}{1 + \frac{2^{\eta + 1} + \log c}{1 - 2^{-\eta}}} \delta$.  

64
We need to (optimally) choose \( \tau \in (0,1) \) to ensure that 
\[
(1 - \tau)\delta = \tau \frac{\log c}{1 + \frac{1}{2\eta + 1 + 2 \log c}} \delta; 
\]
the equality is achieved for \( \tau = \frac{1}{1 + a} \), where 
\[
a = \frac{1}{1 + \frac{1}{2\eta + 1 + 2 \log c}} \frac{1 - 2^{-\eta}}{1 - 2^{-\eta}}
\]
which, once plugged back in 
\[
(1 - \tau)\delta
\]
gives the claimed lower bound for \( s_{VRS}(\delta, n) \). (And thus we have established the second lower bound from Theorem 10.1.) \( \square \)
11 Proof of Theorem 3

In this section we prove Theorem 1, discussed in Section 1.3 and formally stated in Section 2.4.

Proof of Theorem 3. Because the reductions of [BSCGT12] preserve the properties we are going to prove (see Remark 11.1), it suffices to concentrate on our PCP construction for sACSP from the proof of Theorem 7.1.

We thus proceed as follows. We formally introduce universal arguments, along with our relaxation of almost universal arguments (Section 11.1). We then prove that the PCPs from Theorem 7.1 have the relatively-efficient oracle construction property (Section 11.2), have the non-adaptive verifier property (Section 11.3), have the efficient reverse-sampling property (Section 11.4), and the “explicit” proof of knowledge property (Section 11.5). Finally, we show how to construct almost universal arguments using PCPs with these four properties (Section 11.6). Throughout, when providing pseudocode, we freely use procedures defined in Section B.3.

Also, it suffices to prove that our PCP construction for sACSP can be used to construct almost universal arguments, because [Mic00, Val08, CT10, BCCT11, CT12] only need a subset of the properties needed for almost universal arguments.\footnote{More precisely, these latter works require a stronger notion of a non-adaptive verifier than what is required for universal arguments. Namely, (standard) non-adaptivity only requires that the verifier algorithm can be split into a query algorithm and a decision algorithm. A stronger notion of adaptivity further requires that the query algorithm only needs as input a bound on the computation (rather than the actual statement to be proved). Our PCP construction for sACSP does enjoy this stronger notion of non-adaptivity.}

We note that if one wishes to use a PCP system without an efficient reverse sampler, not all is lost: as in prior analyses [Kil92, Mic00], one can still obtain succinct arguments of knowledge for NP by assuming the existence of strong collision-resistant hash functions.

Remark 11.1 (choice of computation model). It suffices to prove the four required properties for our PCP system for (an arbitrary choice of parameters for) sACSP, because any reasonable Levin reduction to sACSP will preserve the four properties;\footnote{Even computational Levin reductions, when properly defined, will preserve these properties; see [BSCGT12].} in particular, so will the Levin reductions from bounded halting problem on RAMs studied by Ben-Sasson et al. [BSCGT12]. Therefore, our focus will be on the PCP system \((P_{\text{sACSP}}, V_{\text{sACSP}})\) that we construct for sACSPs, and so we will prove our results relative to it, assuming that any reductions have already been applied by both the prover and verifier. We thus fix an arbitrary choice of parameters for sACSP.

Remark 11.2 (examples of positive applications). Succinct arguments for NP have been used to achieve cryptographic tasks potentially very useful in practice. Indeed, most such “positive” applications of succinct arguments only consider the verification of computations that lie in NP; in particular, the “full power” of universal arguments (or even almost universal arguments) is usually not needed.\footnote{An exception is the work of Chase and Visconti [CV12], who have shown how to “boost” the knowledge property of a universal argument in order to obtain a secure implementation of a database commitment functionality that hides the input size.}

Theorem 3 can thus be interpreted as alleviating the “succinct-argument bottleneck” that is currently preventing real-world practicality of many desirable cryptographic constructions. Examples of such constructions include:
• **Delegation of computation.** In a *delegation of computation scheme*, a weak party wishes to delegate the computation of a function $F$ on an input $x$ to another (untrusted) more powerful party (who may or may not be allowed to contribute his own input to the computation). If one insists on avoiding expensive offline precomputations, succinct arguments are essentially the only tool for constructing such schemes.\textsuperscript{21}

• **Proof-carrying data.** Chiesa and Tromer \[CT10, CT12\] have shown how to construct non-interactive succinct arguments of knowledge that can be “recursively composed”,\textsuperscript{22} using any (constant-round public-coins) succinct argument in a model where parties have access to a signature functionality. They then show how to use these to construct a *proof-carrying data system*, a cryptographic primitive that is able to dynamically compile a distributed computation into one where a given “local” security property is enforced. Proof-carrying data systems naturally address a number of integrity concerns that arise in systems security, and it would be great if such a powerful primitive could be made more practical.

• **Computationally-sound checkers.** Micali \[Mic98\] showed how non-interactive succinct arguments that are publicly verifiable give rise to *computationally-sound checkers*, a cryptographic primitive that is capable of certifying NP heuristics.

Succinct arguments are also one of the most powerful and beautiful combinations of complexity-theoretic tools (such as PCPs) and cryptographic tools (such as collision-resistant hash functions), and investigating their efficiency is a very exciting research direction with great impact potential to practice.

**Remark 11.3** (computational overheads). The construction of universal arguments starting from a PCP system (with certain properties) and a collision-resistant hash-function family \[BG08\] introduces very little additional computational overhead on top of the PCP system.

Therefore, establishing that almost universal arguments can be constructed, via the same construction as in \[BG08\], using a PCP system with a certain concrete-efficiency threshold $B$ essentially means constructing almost universal arguments with a concrete-efficiency threshold $B'$ not much greater than $B$.\textsuperscript{23}

Other constructions of succinct arguments from PCPs are not as “light”; for example, in \[DCL08, BCCT11, DFH12, GLR11\], one must also use a private information retrieval scheme.

### 11.1 Universal Arguments and Our Relaxation

A **succinct argument** for NP is a computationally-sound interactive proof for NP where, for a given NP language $L$, in order to check membership of a given instance $y$ in $L$, the verifier only needs to run in time that is bounded by $p(\kappa, |y|)$ and the prover only needs to run in time that is

\textsuperscript{21}Sometimes one is also interested in privacy. Such a property can be achieved by properly combining the succinct argument with a fully-homomorphic encryption scheme \[Gen09\]. Fully-homomorphic encryption is another computationally-heavy primitive, whose efficiency has been studied by, e.g., \[GH11b, GH11a, BGV12, GSS12b, GSS12a\]. However, quasilinear-time reductions that are compatible with fully-homomorphic encryption are not known; see \[BSCGT12\].

\textsuperscript{22}Also called succinct hearsay arguments: succinct arguments that can prove statements based on “hearsay”, namely, based on previous proofs.

\textsuperscript{23}It is of course possible to extend the discussion of Section 2.1 about concrete-efficiency thresholds to the case of succinct arguments.
bounded by \( p(\kappa, T) \), where \( T \) is the time to (non-deterministically) evaluate the \( \text{NP} \) verification relation for \( L \) on input \( y \), \( p \) is a fixed polynomial independent of \( L \), and \( \kappa \) is a security parameter that determines the soundness error. A succinct argument of knowledge for \( \text{NP} \) is a succinct argument for \( \text{NP} \) where soundness is strengthened to a proof-of-knowledge property.

Roughly, a universal argument [BG08] is a succinct argument of knowledge for \( \text{NEXP} \), where, in order to check membership of an instance \( y \) in \( L \in \text{NEXP} \), the verifier only needs to run in time that is bounded by \( p(\kappa, |y|, \log T) \) and the prover only needs to run in time that is bounded by \( p(\kappa, T) \), where \( T \) is the time to (non-deterministically) evaluate the verification relation for \( L \) on input \( y \), \( p \) is a fixed polynomial independent of \( L \), and \( \kappa \) is a security parameter.

The difference between universal arguments and almost universal arguments, achieved by our PCPs, relates to the efficiency of the knowledge extractor. Details follow.

Barak and Goldreich [BG08] consider a language defined as follows (once adapted to the case of random-access machines):

**Definition 11.4 (Universal Set).** The universal set, denoted \( S_{\kappa} \), is the set of all triples \( y = (M, x, T) \) such that \( M \) is (the description of) a two-tape random-access machine, \( x \) is a binary string, and \( T \) is a binary integer such that there is a binary string \( w \) for which \( M \) accepts \((x, w)\) within \( T \) steps (where \( x \) is written on the input tape and \( w \) on the witness tape). We denote by \( R_{\kappa} \) the witness relation of the universal set \( S_{\kappa} \), and by \( R_{\kappa}(y) \) the set of valid witnesses for a given triple \( y \).

The name “universal” comes from the fact that every language \( L \) in \( \text{NP} \) is linear-time reducible to \( S_{\kappa} \) by mapping every instance \( x \) to the triple \((M_L, x, 2^{|x|})\), where \( M_L \) a two-tape random-access machine that decides \( L \), so \( S_{\kappa} \) can uniformly handle all \( \text{NP} \) statements.

A universal argument is simply an efficient interactive argument of knowledge for the universal set:

**Definition 11.5.** A universal argument system is a pair of machines \((P_{\text{UA}}, V_{\text{UA}})\) that satisfies the following conditions:

1. Efficient verification: There exists a polynomial \( p \) such that for any \( y = (M, x, T) \), the total time spent by the (probabilistic) verifier strategy \( V_{\text{UA}} \), on common input \( y \), is at most \( p(|y|) = p(|M| + |x| + \log T) \). In particular, all messages exchanged during the interaction have length that is at most \( p(|y|) \).

2. Completeness via a relatively-efficient prover: For every \((M, x, T, w) \in R_{\kappa},\)

\[
\Pr \left[ (P_{\text{UA}}(w), V_{\text{UA}})(M, x, T) = 1 \right] = 1 .
\]

Furthermore, there exists a polynomial \( p \) such that for every \((M, x, T, w) \in R_{\kappa} \) the total time spent by \( P_{\text{UA}}(w) \), on common input \((M, x, T)\), is at most

\[
p\left(|M| + |x| + \text{time}_M(x,w)\right) \leq p(|M| + |x| + T) .
\]

3. Computational soundness: For every family of polynomial-size prover circuits \( \{P_{\kappa}\}_{\kappa \in \mathbb{N}} \) and every positive constant \( c \), for all sufficiently large \( \kappa \in \mathbb{N} \), for every \((M, x, T) \in \{0,1\}^\kappa \setminus S_{\kappa},\)

\[
\Pr \left[ (P_{\kappa}, V_{\text{UA}})(M, x, T) = 1 \right] < \frac{1}{\kappa^c} .
\]
4. Weak proof of knowledge: Implies computational soundness, and is stated below in Definition 11.6.

**Definition 11.6 (Weak Proof of Knowledge).** For every two positive polynomials \( s_{UA} \) and \( p_{UA} \) there exist a positive polynomial \( q_{UA} \) and a probabilistic polynomial-time weak knowledge extractor \( E_{UA} \) such that for every family of \( s_{UA} \)-size prover circuits \( \tilde{P}_{UA} = \{ \tilde{P}_{UA,\kappa} \}_{\kappa \in \mathbb{N}} \), for all sufficiently large \( \kappa \in \mathbb{N} \), for every instance \( y = (M, x, T) \in \{0, 1\}^\kappa \) the following holds:

Suppose that the prover circuit \( \tilde{P}_{UA,\kappa} \) convinces \( V_{UA} \) to accept \( y \) with probability greater than \( p_{UA}(\kappa)^{-1} \) (taken over a random choice of internal randomness for \( V_{UA} \)). Then, with probability greater than \( q_{UA}(\kappa)^{-1} \) taken over a random choice of internal randomness \( r \) for \( E_{UA} \), the weak knowledge extractor \( E_{UA} \), with oracle access to the code of \( \tilde{P}_{UA,\kappa} \) and on input \( y \), is an implicit representation of a valid witness \( w \) for \( y \).

In symbols:

\[
\forall s_{UA} \ \forall p_{UA} \ \exists q_{UA} \ \exists E_{UA} \ \forall s_{UA}\text{-size } \tilde{P}_{UA} \ \exists K \ \forall \kappa > K \ \forall y = (M, x, T) \in \{0, 1\}^\kappa
\]

if

\[
Pr \left[ (\tilde{P}_{UA,\kappa}, V_{UA})(y) = 1 \right] > \frac{1}{p_{UA}(\kappa)} ,
\]

then

\[
Pr \left[ \text{there exists } w = w_1 \cdots w_T \in R_U(y) \text{ such that, } \forall i \in [T], E_{UA}(\tilde{P}_{UA,\kappa}, y, i; r) = w_i \right] > \frac{1}{q_{UA}(\kappa)} .
\]

Note that, in the definition of the weak proof-of-knowledge property, the knowledge extractor \( E_{UA} \) is required to run in probabilistic polynomial-time, while, on the other hand, the size of the witness for a particular instance \( y = (M, x, T) \) may be superpolynomial in \( |y| \); therefore, we can only require that the knowledge extractor is an “implicit representation” of a valid witness. Moreover, both \( E_{UA} \) and \( \tilde{P}' \) may depend on \( p \), so that the proof of knowledge is “weak” in the sense that it does not imply the standard (or, “strong”) proof of knowledge [BG93].

Barak and Goldreich prove the following theorem:

**Theorem 11.7 ([BG08]).** If (standard) collision-resistant hashing schemes exist, then there exist (four-message, public coin) universal arguments.

The weaker form of proof of knowledge that we consider does not insist that the knowledge extractor is an implicit representation of the witness, and thus we call this property **explicit** weak proof of knowledge:

**Definition 11.8 (Explicit Weak Proof of Knowledge).** For every two positive polynomials \( s_{UA} \) and \( p_{UA} \) there exist a positive polynomial \( q_{UA} \) and a probabilistic polynomial-time weak knowledge extractor \( E_{UA} \) such that for every family of \( s_{UA} \)-size prover circuits \( \tilde{P}_{UA} = \{ \tilde{P}_{UA,\kappa} \}_{\kappa \in \mathbb{N}} \), for all sufficiently large \( \kappa \in \mathbb{N} \), for every instance \( y = (M, x, T) \in \{0, 1\}^\kappa \) the following holds:

Suppose that the prover circuit \( \tilde{P}_{UA,\kappa} \) convinces \( V_{UA} \) to accept \( y \) with probability greater than \( p_{UA}(\kappa)^{-1} \) (taken over a random choice of internal randomness for \( V_{UA} \)). Then, with probability greater than \( q_{UA}(\kappa)^{-1} \) taken over a random choice of internal randomness \( r \) for \( E_{UA} \), the weak knowledge extractor \( E_{UA} \), with oracle access to the code of \( \tilde{P}_{UA,\kappa} \) and on input \( (y, 1^T) \), outputs a valid witness \( w \) for \( y \),
In symbols:
\[
\forall s_{\text{UA}} \forall p_{\text{UA}} \exists q_{\text{UA}} \exists E_{\text{UA}} \forall s_{\text{UA}} \text{-size} \exists K \forall \kappa > K \forall y = (M, x, T) \in \{0, 1\}^\kappa
\]

if
\[
\Pr\left[\langle \tilde{P}_{\text{UA}, \kappa}, V_{\text{UA}} \rangle(y) = 1\right] > \frac{1}{p_{\text{UA}}(\kappa)},
\]

then
\[
\Pr_r \left[ w \in R_U(y) \mid E_{\text{UA}}^{\langle \tilde{P}_{\text{UA}, \kappa} \rangle}(y, 1^T; r) = w \right] > \frac{1}{q_{\text{UA}}(\kappa)}.
\]

We thus define almost universal arguments as universal arguments where the proof of knowledge property is relaxed to that of Definition 11.8.

**Definition 11.9.** An almost universal argument system \((P_{\text{UA}}, V_{\text{UA}})\) satisfies [BG08, Definition 2.1], except that the (implicit) weak proof-of-knowledge property is replaced by the explicit weak proof-of-knowledge property.

As discussed already in Remark 11.1 in Section 2, we will not consider a “natural” universal language (such as the universal language relative to random-access machines or relative to Turing machines), but we will concentrate on sACSPs because the properties we shall prove will remain “invariant” under appropriate Levin reductions. In such a case, instances consist of triples \(y = (\text{par}_{\text{sACSP}}, x, 1^t)\), where \(\text{par}_{\text{sACSP}}\) is a choice of parameters for sACSP and \((x, 1^t) \in \text{sACSP}(\text{par}_{\text{sACSP}})\). Throughout, we fix a choice of \(\text{par}_{\text{sACSP}}\), so that it will suffice to specify the pair \((x, 1^t)\).

### 11.2 Relatively-Efficient Oracle Construction

The first property considered by Barak and Goldreich [BG08, Definition 3.2, first item] for a PCP verifier is the existence of an efficient prover that is able to produce accepting PCP oracles whenever they exist:

**Definition 11.10** (Relatively-Efficient Oracle Construction). A PCP verifier \(V\) has the relatively-efficient oracle construction property if there exists a polynomial-time algorithm \(P\) such that, on input any \((x, w) \in R\), algorithm \(P\) outputs an oracle \(\pi_x\) that makes \(V\) always accept.

We remark the PCP verifier \(V_{\text{sACSP}}\) does satisfy the definition above:

**Claim 11.11.** The PCP verifier \(V_{\text{sACSP}}\) has the relatively-efficient oracle construction property for the relation induced by the language sACSP.

**Proof.** From Theorem 7.1 we know that the PCP prover \(P_{\text{sACSP}}\) does run in polynomial time. □

Clearly, this first property is the easiest property to establish because it is natural to most PCP constructions and, in our specific case, comes “for free” from our previous discussions (indeed, we have worked hard to make the PCP prover not only efficient but also fast!).

70
11.3 Non-Adaptive Verifier

The second property considered by Barak and Goldreich [BG08, Definition 3.2, second item] for a PCP verifier is the non-adaptivity of the queries:

**Definition 11.12** (Non-Adaptive PCP Verifier). A PCP verifier $V$ is **non-adaptive** if its queries are based only on the input and its internal coin tosses, independently of the answers given to previous queries. That is, $V$ can be decomposed into a pair of algorithms $Q$ and $D$ such that on input $x$ and a random tape $r$, the verifier makes the query sequence $Q(x,r,1),\ldots,Q(x,r,p(|x|))$, obtains the answers $b_1,\ldots,b_{p(|x|)}$, and decides according to the decision of $D(x,r,b_1\cdots b_{p(|x|)})$, where $p$ is some fixed polynomial.

We prove that the PCP verifier $V_{\text{sACSP}}$ does satisfy the definition above. While, at high level, this may be easy to see by inspection of the construction of $V_{\text{sACSP}}$, we believe it necessary to spell out in careful detail the proof that this is the case, because the “decomposition” of the verifier $V_{\text{sACSP}}$ into a query algorithm and a decision algorithm is needed if one is interested in studying the concrete efficiency of universal arguments.

**Claim 11.13.** The PCP verifier $V_{\text{sACSP}}$ is a non-adaptive PCP verifier.

The construction of $V_{\text{sACSP}}$ is quite complicated, so we will have to proceed one step at a time. To begin with, as $V_{\text{sACSP}}$ is constructed using (both standard and strong) PCPP verifiers, we also need to specify what we mean by a non-adaptive PCPP verifier:

**Definition 11.14** (Non-Adaptive PCPP Verifier). A PCPP verifier $V$ is **non-adaptive** if its queries are based only on the explicit input and its internal coin tosses, independently of the answers given to previous queries. That is, $V$ can be decomposed into a pair of algorithms $Q$ and $D$ such that on explicit input $x$ and a random tape $r$, the verifier makes the query sequence $Q(x,r,1),\ldots,Q(x,r,p(|x|))$, obtains the answers $b_1,\ldots,b_{p(|x|)}$, and decides according to $D(x,r,b_1\cdots b_{p(|x|)})$, where $p$ is some fixed polynomial.

Our proof will be “bottom up”. Please refer to Figure 1 for an algorithmic reference of the construction of $V_{\text{sACSP}}$. (More specific references will be given in each of the proofs.) Also, throughout, we fix a specific choice of parameters $(\eta,\kappa_0,\gamma,\mu)$, which parametrize $V_{\text{sACSP}}$. Finally, we will not carry out a complexity analysis for the “non-adaptively decomposed” verifiers, as a detailed analysis for the “non-decomposed” verifiers was already carried out in Section C.

**Remark 11.15.** Note that the alphabet of proof oracles (as well as implicit inputs) are elements of a finite field $\mathbb{F}_{2^\ell}$, and not bits. Thus, our descriptions of $Q$ and $D$ will reason about indexing into strings of such field elements. The departure from binary oracles is mostly inconsequential, with the exception of a minor note that will come up later in the proof of almost universal arguments. (See Remark 11.41.)

11.3.1 Non-Adaptivity of $V_{\text{RS,\ell}}$

**Lemma 11.16.** $V_{\text{RS,\ell}}$ is a non-adaptive (strong) PCPP verifier.

**Proof.** The explicit input of $V_{\text{RS,\ell}}$ is $(I_\ell,B_L,\mathcal{O}_L)$, where $I_\ell$ is an irreducible polynomial over $\mathbb{F}_2$ of degree $\ell$ with root $x$, which induces the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$, and $B_L = (a_1,\ldots,a_\kappa)$ and $\mathcal{O}_L$ are the basis and the offset of a $\kappa$-dimensional affine subspace $L \subseteq \mathbb{F}_{2^\ell}$; the implicit input
of \(V_{\text{RS},=}\) is a function \(p: L \rightarrow \mathbb{F}_{2^\ell}\). (For more details on the algorithm \(V_{\text{RS},=}\), see Algorithm 16.) The proof of proximity \(\pi\) of \(V_{\text{RS},=}\) is parsed as a pair \((f, \Pi)\), where \(f\) is a bivariate function over a subset of \(\mathbb{F}_{2^\ell} \times \mathbb{F}_{2^\ell}\) and \(\Pi\) is a sequence of proofs of proximity for Reed-Solomon codes over (smaller) affine subspaces; see Algorithm 7 (and references therein) for the formal definition and for the algorithm that computes the proof of proximity.\(^{24}\) Finally, see Lemma C.1 for query\(_{\text{RS},=}(\ell, \kappa)\), \(\text{rand}_{\text{RS},=}(\ell, \kappa)\), and length\(_{\text{RS},=}(\ell, \kappa)\).

The algorithm \(V_{\text{RS},=}\) is recursive, and all its queries to the implicit input and proof of proximity are made during its “base case”, which occurs when \(\dim(L) \leq \kappa_0\); the base case queries every value of the function found in the implicit input, thus obtaining a codeword \(\alpha_1 \cdots \alpha_{2^\ell}\), and then directly verifies whether \(\alpha_1 \cdots \alpha_{2^\ell}\) is in RS(\(\mathbb{F}_{2^\ell}, L, |L|/2^n - 1\)) or not (and accepts or rejects accordingly), where \(d_{\kappa,\eta} := |L|/2^n - 1 = 2^\ell - 1\); since \(\dim(L) \leq \kappa_0\), there are at most \(2^{\kappa_0}\) values to query.

Therefore, at high level, the query algorithm \(Q_{\text{RS},=}\) will be the algorithm that produces all the queries of the base case, while the decision algorithm \(D_{\text{RS},=}\) will be the logic used by the base case to accept or reject, when given the answers to the (at most \(2^{\kappa_0}\)) queries.

However, in the case of \(Q_{\text{RS},=}\), the recursive nature of \(V_{\text{RS},=}\) makes things slightly more complicated, because the implicit inputs used by recursive calls are “simulated” by the callers; thus, we must recursively “translate” queries, starting from the base case, to understand what “real” queries are made by the top-level algorithm (whose implicit input is not simulated by any other procedure), thus allowing us to write down \(Q_{\text{RS},=}\). (Note that, unlike implicit inputs, proofs of proximity for recursive calls are already contained in the proof of proximity of the caller, and thus have no need to be simulated; consequently, we do not have to worry about translating queries to them.)

Similarly, also in the case of \(D_{\text{RS},=}\), the recursive nature of \(V_{\text{RS},=}\) makes things slightly more complicated, because the interpolation performed by \(D_{\text{RS},=}\) (as part of its verification test) needs to know which affine subspace of \(\mathbb{F}_{2^\ell}\) is the domain of the function contained in the implicit input; this information depends on which recursive calls occurred starting from the top-level algorithm all the way down to the base case.

We now proceed to a detailed description of the algorithm \(Q_{\text{RS},=}\), and then for the algorithm \(D_{\text{RS},=}\).

The “hard work” (mainly, bookkeeping) in \(Q_{\text{RS},=}\) is carried out by an iterative procedure that we call TRANSFORM; on input an irreducible polynomial \(I_\ell\) of degree \(\ell\), a basis \(B_L\) and offset \(O_L\) for a \(\kappa\)-dimensional affine subspace \(L \subseteq \mathbb{F}_{2^\ell}\), a random string \(r \in \{0, 1\}\) \(\text{rand}_{\text{RS},=}(\ell, \kappa)\) for the verifier, and an index \(i \in \{1, \ldots, \text{query}_{\text{RS},=}(\ell, \kappa)\}\), the procedure TRANSFORM outputs a triple \((\text{text}, \text{elt}, j)\), where \(j \in \{1, \ldots, |L| + \text{length}_{\text{RS},=}(\ell, \kappa)\}\) is an index into the concatenation of the implicit input and proximity proof (which is a string of field elements) corresponding to the \(i\)-th query performed by \(V_{\text{RS},=}\) on input \((I_\ell, B_L, O_L)\) and random string \(r\); the other two components, \(\text{text} \in \{\text{“implicit-input”, “proximity-proof”}\}\) and \(\text{elt} \in L \cup \{S \cup T\}\), are additional information used by the iterative procedure.

Thus, the algorithm \(Q_{\text{RS},=}\) is as follows:

\(^{24}\) In fact, for the purpose of this proof, we change slightly the definition of the proof of proximity. Specifically, we let \(f\) be a bivariate function over \(S \cup T\), as opposed to only over \(S\); the values of \(f\) on \(T\) will never be used, but including them facilitates bookkeeping of indices. (Bhattacharyya [Bha05] already employed this slight change in his implementation of \(V_{\text{RS},=}\), as can be verified by inspection of his code, and as reflected in the proof length analysis in [Bha05, Section 2.2.2], where the function \(f\) is reported to require space \(|L_1| \cdot |L_\beta| = |L_1| \cdot (8 \cdot |L_0|) = 2^{\ell/2} \cdot (8 \cdot 2^{\ell/2})\), instead of \(|L_1| \cdot |L_\beta| - (L_0 + \beta + O_L)| = |L_1| \cdot (7 \cdot |L_0|)\).)
Q_{RS, \kappa}(I, \mathcal{B}_L, \mathcal{O}_L, r_1 \cdots r_{\text{rand}_{RS, \kappa(t, \kappa)}, i}) \equiv

1. Compute $(\text{text}, \text{elt}, j) := \text{TRANSLATE}(I, \mathcal{B}_L, \mathcal{O}_L, r, i)$.
2. Output $j$.

The algorithm for \textsc{Translate} is the simple strategy that keeps track of index translation (cf. index translation in [BSS08, Section 6.3]) and indexes into the concatenation of the implicit input and proximity proof:

$$\text{TRANSLATE}(I, \mathcal{B}_L, \mathcal{O}_L, r_1 \cdots r_{\text{rand}_{RS, \kappa(t, \kappa)}, i}) \equiv$$

1. If $\kappa \leq \kappa_0$, then do the following:
   a. $\alpha_i := \text{GetEltWithIndex}(I, \mathcal{B}_L, \mathcal{O}_L, i)$;
   b. text := “implicit-input”;
   c. elt := $\alpha_i$;
   d. output $(\text{text}, \text{elt}, i)$.
2. If $\kappa > \kappa_0$, then do the following:
   a. $\mathcal{B}_{L_0} := (a_1, \ldots, a_{\lfloor \kappa/2 \rfloor - \gamma})$, $\mathcal{O}_{L_0} := \mathcal{O}_L$;
   b. $\mathcal{B}_{L_0} := (a_1, \ldots, a_{\lfloor \kappa/2 \rfloor - \gamma + \mu})$, $\mathcal{O}_{L_0} := \mathcal{O}_L$;
   c. $[Z_{L_0}]^\alpha := \text{FINDSUBPOLY}(I, \mathcal{B}_{L_0}, \mathcal{O}_{L_0})$;
   d. if $r_1 = 0$, then do \text{row test} translation:
      i. $m := 1 + \lfloor \kappa/2 \rfloor + \gamma$;
      ii. $\mathcal{B}_{L_1} := (a_{\lfloor \kappa/2 \rfloor - \gamma + 1}, \ldots, a_\kappa)$, $\mathcal{O}_{L_1} := \mathcal{O}_L$;
      iii. $\beta := \text{GetRAND}(I, \mathcal{B}_{L_1}, \mathcal{O}_{L_1}, r_2 \cdots r_{1 + \lfloor \kappa/2 \rfloor + \gamma})$;
      iv. $\beta' := [Z_{L_0}]^\alpha(\beta)$;
      v. $t_\beta := \text{INDEXOFELT}(I, \mathcal{B}_{L_1}, \mathcal{O}_{L_1}, \beta)$;
      vi. if $\beta \in L_0$, then $\mathcal{B}_{L_0} := (a_1, \ldots, a_{\lfloor \kappa/2 \rfloor - \gamma + \mu}, a_{\lfloor \kappa/2 \rfloor - \gamma + \mu + 1})$;
      vii. if $\beta \not\in L_0$, then $\mathcal{B}_{L_0} := (a_1, \ldots, a_{\lfloor \kappa/2 \rfloor - \gamma + \mu}, \beta + \mathcal{O}_{L_0})$;
   v. $\mathcal{O}_{L_0} := \mathcal{O}_{L_0}$;
   vi. $(\text{text}', \text{elt}', i) := \text{TRANSLATE}(I, \mathcal{B}_{L_0}, \mathcal{O}_{L_0}, r_{m+1} \cdots r_{\text{rand}_{RS, \kappa(t, \kappa), i}})$;
   x. if $\text{text}'$ = “implicit-input”, then:
      A. parse elt' as an element $\alpha \in L_\beta$;
      B. $\alpha' := [Z_{L_0}]^\alpha(\alpha)$;
      C. if $\alpha' = \beta'$, then:
         - text := “implicit-input”;
         - elt := $\alpha$;
         - $i := \text{INDEXOFELT}(I, \mathcal{B}_L, \mathcal{O}_L, \alpha)$;
         - output $(\text{text}, \text{elt}, i)$;
      D. if $\alpha' \neq \beta'$, then:
         - text := “proximity-proof”;
         - elt := $(\alpha, \beta')$;
         - $i := |L| + |L_\beta| \cdot (t_\beta - 1) + 1$;
         - output $(\text{text}, \text{elt}, i)$;
   xi. if $\text{text}'$ = “proximity-proof”, then:
      A. text := text';
      B. elt := elt';
      C. $i := (1 - |L_\beta| + |L| + |L_\beta| \cdot (t_\beta - 1) \cdot \text{length}_{RS, \kappa}(t, \dim L_\beta)$;
      D. output $(\text{text}, \alpha, i)$;
   (e) if $r_1 = 1$, then do \text{column test} translation:
      i. $m := 1 + \lfloor \kappa/2 \rfloor - \gamma + \mu$;
      ii. $\alpha := \text{GetRAND}(I, \mathcal{B}_{L_0}, \mathcal{O}_{L_0}, r_2 \cdots r_{1 + \lfloor \kappa/2 \rfloor - \gamma + \mu})$;
      iii. $\alpha' := [Z_{L_0}]^\alpha(\alpha)$;
      iv. $t_\alpha := \text{INDEXOFELT}(I, \mathcal{B}_{L_0}, \mathcal{O}_{L_0}, \alpha)$;
      v. $\mathcal{B}_{Z_{L_0}(L_1)} := ([Z_{L_0}]^\alpha(a_{\lfloor \kappa/2 \rfloor - \gamma + 1}) + [Z_{L_0}]^\alpha(0_{2^\gamma}), \ldots, [Z_{L_0}]^\alpha(a_\kappa) + [Z_{L_0}]^\alpha(0_{2^\gamma}))$;
vi. \( O_{Z_L}(L_i) := [Z_{L_0}]^\#(O_{L_i}) \);

vii. (text', elt, i) := TRANSLATE\((I_{\ell}, B_{Z_L}(L_i), O_{Z_L}(L_i), r_{m+1} \cdots r_{\text{rand}_{\text{RS},=(\ell,\kappa)}}(i), i)\);

viii. if text' = "implicit-input", then:
A. parse elt' as an element \( \beta' \in Z_L(L_i) \);
B. if \( \alpha' = \beta' \), then:
   - text := "implicit-input";
   - elt := \( \alpha' \);
   - \( i := \text{GETINDEXOFELT}(I_{\ell}, B_L, \alpha') \);
   - output (text, elt, \( i \));
C. if \( \alpha' \neq \beta' \), then:
   - text := "proximity-proof";
   - elt := \( (\alpha', \beta') \);
   - \( i := |L| + |L_{\beta'}| \cdot (t - 1) + t_{\alpha} \);
   - output (text, elt, \( i \));

ix. if text' = "proximity-proof", then:
A. text := text';
B. elt := elt';
C. \( i := (t - |Z_L(L_i)| + |L|) + |L_{\beta'}| \cdot |L_{\beta'}| + |L_{\beta'}| \cdot \text{length}_{\text{RS},=(\ell, \dim L_{\beta'})} + (t_{\alpha} - 1) \cdot \text{length}_{\text{RS},=(\ell, \dim Z_L(L_i))} \);
D. output (text, \( i \)).

The algorithm for \( D_{\text{RS},=}(I_{\ell}, B_L, O_L), r_1 \cdots r_{\text{rand}_{\text{RS},=(\ell,\kappa)}}, \alpha_1 \cdots \alpha_{2^n} \) \)

1. If \( \kappa \leq \kappa_0 \), then:
   a. \( d_{\kappa,\kappa} := 2^n/2^n - 1 \);
   b. \( P := \text{SUBSPACEINTERP}(I_{\ell}, B_L, O_L, (\alpha_1, \ldots, \alpha_{2^n})) \);
   c. \( \bar{d} := \deg(P) \);
   d. if \( \bar{d} \leq d_{\kappa,\kappa} \), output 1, else output 0

2. If \( \kappa > \kappa_0 \), then:
   a. \( B_{L_0} := (a_1, \ldots, a_\gamma, \ldots, a_{\kappa/2 - \gamma}, \ldots, a_k), O_{L_0} := O_L \);
   b. \( [Z_{L_0}]^\# := \text{FINDSUBSPOLY}(I_{\ell}, B_{L_0}, O_{L_0}) \);
   c. \( B_{L_0} := (a_1, \ldots, a_\gamma, \ldots, a_{\kappa/2 - \gamma + \mu}), O_{L_0} := O_L \);
   d. if \( r_1 = 0 \), then do row test recursion:
      i. \( m := 1 + [\kappa/2] + \gamma \);
      ii. \( B_{L_1} := (a_{\gamma + 1}, \ldots, a_k), O_{L_1} := O_L \);
      iii. \( \beta := \text{GETRAND}(I_{\ell}, B_{L_1}, O_{L_1}, r_2 \cdots r_1 + \gamma) \);
      iv. if \( \beta \in L_{L_0} \), then \( B_{L_0} := (a_1, \ldots, a_\gamma, \ldots, a_{\kappa/2 - \gamma + \mu}, a_{\kappa/2 - \gamma + \mu + 1}) \);
      v. if \( \beta \notin L_{L_0} \), then \( B_{L_0} := (a_1, \ldots, a_{\gamma + 1}, \beta + O_{L_0}) \);
      vi. \( O_{L_{\beta}} := O_{L_0} \);
   vii. output \( D_{\text{RS},=(I_{\ell}, B_{L_{\beta}}, O_{L_{\beta}}), r_m+1 \cdots r_{\text{rand}_{\text{RS},=(\ell,\kappa)}}, \alpha_1 \cdots \alpha_{2^n}} \);
   e. if \( r_1 = 1 \), then do column test recursion:
      i. \( m := 1 + [\kappa/2] + \gamma + \mu \);
      ii. \( \alpha := \text{GETRAND}(I_{\ell}, B_{L_{\beta}}, O_{L_{\beta}}, r_2 \cdots r_1 + [\kappa/2] - \gamma + \mu) \);
      iii. \( B_{Z_{L_0}(L_i)} := ([Z_{L_0}]^\#(a_{\gamma + 1}) + [Z_{L_0}]^\#(0_{\ell,\kappa}) \cdots [Z_{L_0}]^\#(a_k) + [Z_{L_0}]^\#(0_{\ell,\kappa})) \);
      iv. \( O_{Z_{L_0}(L_i)} := [Z_{L_0}]^\#(O_{L_1}) \);
      v. output \( D_{\text{RS},=(I_{\ell}, B_{Z_{L_0}(L_1)}, O_{Z_{L_0}(L_1)}), r_m+1 \cdots r_{\text{rand}_{\text{RS},=(\ell,\kappa)}}, \alpha_1 \cdots \alpha_{2^n}} \).
The correctness of both \( Q_{RS,=} \) and \( D_{RS,=} \) easily follows by inspection of the algorithms and the above discussion. \( \square \)

11.3.2 Non-Adaptivity of \( V_{RS,<} \)

**Lemma 11.17.** \( V_{RS,<} \) is a non-adaptive (strong) PCPP verifier.

**Proof.** The explicit input of \( V_{RS,<} \) is \((I_\ell, B_\ell, O_\ell, d)\), where \( I_\ell \) is an irreducible polynomial over \( \mathbb{F}_2 \) of degree \( \ell \) with root \( x \), which induces the field extension \( \mathbb{F}_{2^\ell} := \mathbb{F}_2(x) \), \( B_\ell = (a_1, \ldots, a_\kappa) \) and \( O_\ell \) are a basis and offset of a \( \kappa \)-dimensional affine subspace \( S \subseteq \mathbb{F}_{2^\ell} \), and \( d \) is a positive integer that is less than \( d_{\kappa,\eta} := |S|/2^{\eta} - 1 = 2^{\kappa-\eta} - 1 \); the implicit input of \( V_{RS,<} \) is a function \( p: S \to \mathbb{F}_{2^\ell} \).

(For more details on the algorithm \( V_{RS,<} \), see Algorithm 15.) The proof of proximity \( \pi \) of \( V_{RS,<} \) is parsed as a pair \((\pi_1, \pi_2)\), where both \( \pi_1 \) and \( \pi_2 \) are proofs of proximity to \( RS(\mathbb{F}_{2^\ell}, S, d_{k,n})\); again, see Algorithm 6 for more details and for the algorithm that computes the proof of proximity. Finally, see Lemma C.2 for \( query_{RS,<}(\ell, \kappa, d) \), \( rand_{RS,<}(\ell, \kappa, d) \), and \( length_{RS,<}(\ell, \kappa, d) \).

The algorithm \( V_{RS,<} \) simply calls \( V_{RS,=} \) twice with different inputs, and hence makes at most \( query_{RS,<}(\ell, \kappa, d) := 2 \cdot query_{RS,=}(\ell, \kappa) \) queries. Thus, the algorithm \( Q_{RS,<} \) calls \( Q_{RS,=} \) and then, depending on whether the query was in the first set of \( query_{RS,=}(\ell, \kappa) \) queries or in the second set of \( query_{RS,=}(\ell, \kappa) \) queries, does not shift or shifts by the right amount the index output by \( Q_{RS,=} \).

Thus, the algorithm \( Q_{RS,<} \) is defined as follows:

\[
Q_{RS,<}\left((I_\ell, B_\ell, O_\ell, d), r_1 \cdots r_{\text{rand}_{RS,<}(\ell,\kappa,d)}, i\right) \equiv \\
1. \text{If } i \in \{1, \ldots, query_{RS,=}(\ell, \kappa)\}, \text{ then:} \\
   (a) r'_1 \cdots r'_{\text{rand}_{RS,=}(\ell, \kappa)} := r_1 \cdots r_{\text{rand}_{RS,=}(\ell, \kappa)}; \\
   (b) j := Q_{RS,=}\left((I_\ell, B_\ell, O_\ell), r'_1 \cdots r'_{\text{rand}_{RS,=}(\ell, \kappa)}, i\right); \\
   (c) \text{output } j. \\
2. \text{If } i \in \{1, \ldots, query_{RS,=}(\ell, \kappa)\}, \text{ where } i := i - query_{RS,=}(\ell, \kappa), \text{ then:} \\
   (a) r''_1 \cdots r''_{\text{rand}_{RS,=}(\ell, \kappa)} := r_1 \cdots r_{\text{rand}_{RS,=}(\ell, \kappa)}; \\
   (b) j_0 := Q_{RS,=}\left((I_\ell, B_\ell, O_\ell), r''_1 \cdots r''_{\text{rand}_{RS,=}(\ell, \kappa)}, i\right); \\
   (c) \text{if } 0 < j_0 \leq |S|, \text{ then } j := j_0; \\
   (d) \text{if } |S| < j_0 \leq |S| + length_{RS,=}(\ell, \kappa), \text{ then } j := length_{RS,=}(\ell, \kappa) + j_0; \\
   (e) \text{output } j.
\]

(Note that it just so happens that \( Q_{RS,=} \) is independent of \( d \).) Note that, in Step 2, we need to “shift left” the query by \( query_{RS,=}(\ell, \kappa) \) before feeding it to \( Q_{RS,=} \) and, after invoking \( Q_{RS,=} \), we may need to “shift right” its output index, depending if it is to the explicit input or the proximity proof.

The corresponding algorithm \( D_{RS,=} \) is defined as follows:

\[
D_{RS,<}\left((I_\ell, B_\ell, O_\ell, d), r_1 \cdots r_{\text{rand}_{RS,<}(\ell,\kappa,d)}, \alpha_1 \cdots \alpha_{\text{query}_{RS,<}(\ell,\kappa,d)}\right) \equiv \\
\text{Note that } V_{RS,<} \text{ uses its own implicit input as the implicit input to the first call of } V_{RS,=} \text{, while it simulates the implicit input to the second call of } V_{RS,=} \text{; it turns out that this simulation for the second call of } V_{RS,=} \text{ does not require us to modify the indices returned by } Q_{RS,=} \text{ for queries in the second set of } query_{RS,=}(\ell, \kappa) \text{ queries (besides, shifting the indices by the right amount, that is). (Indeed, simulating a query to } p'(\alpha) = p(\alpha) \cdot Q(\alpha) \text{ by querying } p(\alpha) \text{ and multiplying the result by } Q(\alpha) \text{ has the obvious property that the values of } p' \text{ and those of } p \text{ appear in the same order in the evaluation tables of either.)}
\]

75
1. Parse $\alpha_1 \cdots \alpha_{\text{query}_{RS,<}}(\ell, \kappa, d)$ as $\alpha'_1 \cdots \alpha'_{\text{query}_{RS,<}}(\ell, \kappa) \alpha''_1 \cdots \alpha''_{\text{query}_{RS,<}}(\ell, \kappa)$.
2. $r'_1 \cdots r'_{\text{rand}_{RS,<}}(\ell, \kappa) := r_1 \cdots r_{\text{rand}_{RS,<}}(\ell, \kappa)$.
3. $b_1 := D_{RS,<}(I_\ell, B_S, O_S), r'_1 \cdots r'_{\text{rand}_{RS,<}}(\ell, \kappa), \alpha'_1 \cdots \alpha'_{\text{query}_{RS,<}}(\ell, \kappa)$.
4. $r''_1 \cdots r''_{\text{rand}_{RS,<}}(\ell, \kappa) := r_1 \cdots r_{\text{rand}_{RS,<}}(\ell, \kappa)$.
5. $d_{\kappa, \eta} := \lfloor S/2^n \rfloor - 1$.
6. For $i = 1, \ldots, \text{query}_{RS,<}(\ell, \kappa)$, do the following:
   (a) $j_0 := Q_{RS,<}(I_\ell, B_S, O_S, r''_1 \cdots r''_{\text{rand}_{RS,<}}(\ell, \kappa), i)$;
   (b) if $0 < j_0 \leq |S|$, then:
      i. $\gamma_{j_0} := \text{GETLTWITHINDEX}(I_\ell, B_S, O_S, j_0)$;
      ii. reset $\alpha''_i$ to the new value $\gamma_{j_0} - d_{\kappa, \eta} - d$.
7. $b_2 := D_{RS,<}(I_\ell, B_S, O_S), r''_1 \cdots r''_{\text{rand}_{RS,<}}(\ell, \kappa), \alpha'_1 \cdots \alpha'_{\text{query}_{RS,<}}(\ell, \kappa)$.
8. $b := b_1 \wedge b_2$.

(Note that it just so happens that $D_{RS,<}$ is independent of $d$.) Note that $D_{RS,<}$ is given as input two sets of query answers $\alpha'_1 \cdots \alpha'_{\text{query}_{RS,<}}(\ell, \kappa)$ and $\alpha''_1 \cdots \alpha''_{\text{query}_{RS,<}}(\ell, \kappa)$, and invokes $D_{RS,<}$ once on each; also, before invoking $D_{RS,<}$ on the second set $\alpha'_1 \cdots \alpha'_{\text{query}_{RS,<}}(\ell, \kappa)$, $D_{RS,<}$ has to first multiply the values to simulate answers from the function $p \cdot x^{d_{\kappa, \eta} - d}$ instead of $p$.

The correctness of both $Q_{RS,<}$ and $D_{RS,<}$ easily follows by inspection of the algorithms and the above discussion, as well as Lemma 11.16. 

11.3.3 Non-Adaptivity of $V_{RS, >}$

Lemma 11.18. $V_{RS, >}$ is a non-adaptive (strong) PCPP verifier.

Proof. The explicit input of $V_{RS, >}$ is $(I_\ell, B_S, O_S, d)$, where $I_\ell$ is an irreducible polynomial over $F_2$ of degree $\ell$ with root $x$, which induces the field extension $F_{2^\ell} := F_2(x)$, $B_S = (a_1, \ldots, a_n)$ and $O_S$ are a basis and offset of a $\kappa$-dimensional affine subspace $S$ of $F_{2^\ell}$, and $d$ is a positive integer that is greater than $d_{\kappa, \eta} := |S|/2^n - 1 = 2^\kappa - \eta - 1$; the implicit input of $V_{RS,<}$ is a function $p : S \to F_{2^\ell}$.

(For more details on the algorithm $V_{RS, >}$, see Algorithm 14.) The proof of proximity $\pi$ of $V_{RS, >}$ is parser as a $2^n$-tuple of pairs $((p_0, \pi_0), \ldots, (p_{2^n-1}, \pi_{2^n-1}))$, where $p_0, \ldots, p_{2^n-1}$ are functions from $S$ to $F_{2^\ell}$ and $\pi_0, \ldots, \pi_{2^n-1}$ are proofs of proximity to $\text{RS}(F_{2^\ell}, S, d_0), \ldots, \text{RS}(F_{2^\ell}, S, d_{2^n-1})$, where $d_0, \ldots, d_{2^n-1}$ are the $2^n$ unique non-negative integers such that a polynomial $P(x)$ of degree $d < |S| = 2^n(d_{\kappa, \eta} + 1)$ can be written as a sum $\sum_{i=0}^{2^n-1} x^{\ell(d_{\kappa, \eta} + 1)} P_i(x)$ with $\deg P_i = d_i \leq d_{\kappa, \eta}$; see Algorithm 5 (and the references therein) for more details and for the algorithm that computes the proof of proximity. Finally, see Lemma C.3 for $\text{query}_{RS, >}(\ell, \kappa, d)$, $\text{rand}_{RS, >}(\ell, \kappa, d)$, and $\text{length}_{RS, >}(\ell, \kappa, d)$.

Let $m_{\kappa, \eta, d} := (d+1)/(d_{\kappa, \eta} + 1)$. The algorithm $V_{RS, >}$ does some “real” verification only in the case $d < |S| = 2^n$, for otherwise it can always accept because $\text{RS}(F_{2^\ell}, S, d)$ includes all the codewords (of length $|S|$). Hence, $d_{\kappa, \eta} < d < |S| = 2^n(d_{\kappa, \eta} + 1)$, and thus $m_{\kappa, \eta, d} \in \{0, \ldots, 2^n\}$. The algorithm $V_{RS, >}$ makes $m_{\kappa, \eta, d}$ calls to $V_{RS,<}$, and, in case $m_{\kappa, \eta, d} \cdot (d_{\kappa, \eta} + 1) < (d+1)$, also one call to $V_{RS,<}$; after that, it performs a consistency test by querying at one value the implicit input and at one value each of the functions $p_0, \ldots, p_{2^n}$ in the proximity proof (for a total of $1 + 2^n$ additional queries).

Thus, the algorithm $Q_{RS, >}$ is defined as follows:

$$Q_{RS, >}(I_\ell, B_S, O_S, d, r_1 \cdots r_{\text{rand}_{RS, >}}(\ell, \kappa, d), i)$$
1. If \( d \geq 2^k \), then output \( \bot \). (Because the decision algorithm \( D_{RS,>} \) will accept without examining any answer to any query.)

2. If \( d < 2^k \), then:
   (a) \( d_{\kappa,\eta} := |S|/2^\eta - 1 \);
   (b) \( m_{\kappa,\eta,d} := [(d + 1)/(d_{\kappa,\eta} + 1)] \);
   (c) \( d_{\kappa,\eta,d} := d - m_{\kappa,\eta,d} \cdot (d_{\kappa,\eta} + 1) \);
   (d) if \( i \in \{1, \ldots, m_{\kappa,\eta,d} \cdot \text{query}_{RS,=}(\ell, \kappa)\} \), then:
      i. \( z := [(i - 1)/\text{query}_{RS,=}(\ell, \kappa)] \);
      ii. \( r_1(z) \cdots r_{\text{rand}_{RS,=}(\ell, \kappa)} := r_1 \cdots r_{\text{rand}_{RS,=}(\ell, \kappa)} \);
      iii. \( i' := i - z \cdot \text{query}_{RS,=}(\ell, \kappa) \);
      iv. \( j_0 := \text{Q}_{RS,<}(I_\ell, B_S, O_S), r_1(z) \cdots r_{\text{rand}_{RS,=}(\ell, \kappa)}, i' \);
      v. \( j := |S| + z \cdot (|S| + \text{length}_{RS,=}(\ell, \kappa)) + j_0 \);
      vi. output \( j \);
   (e) if \( m_{\kappa,\eta,d} \cdot (d_{\kappa,\eta} + 1) < d + 1 \) and \( i' \in \{1, \ldots, \text{query}_{RS,=}(\ell, \kappa, d)\} \), where \( i' := i - m_{\kappa,\eta,d} \cdot \text{query}_{RS,=}(\ell, \kappa) \), then:
      i. \( r_1(z) \cdots r_{\text{rand}_{RS,<}(\ell, \kappa, d_{\kappa,\eta}, d) := r_1 \cdots r_{\text{rand}_{RS,<}(\ell, \kappa, d_{\kappa,\eta}, d)} \);
      ii. \( j_0 := \text{Q}_{RS,<}(I_\ell, B_S, O_S, d_{\kappa,\eta,d}, r_1(z) \cdots r_{\text{rand}_{RS,<}(\ell, \kappa, d_{\kappa,\eta}, d)}), i' \);
      iii. \( j := |S| + m_{\kappa,\eta,d} \cdot (|S| + \text{length}_{RS,=}(\ell, \kappa)) + j_0 \);
      iv. output \( j \);
   (f) if \( m_{\kappa,\eta,d} \cdot (d_{\kappa,\eta} + 1) = d + 1 \) and \( i_0 \in \{1, \ldots, 1 + 2^\eta\} \), where \( i_0 := i - m_{\kappa,\eta,d} \cdot \text{query}_{RS,=}(\ell, \kappa) \), then:
      i. \( r_1(z) \cdots r_{\gamma} := r_1 \cdots r_{\kappa} \);
      ii. \( \gamma := \text{GETRAND}_{I_\ell, B_S, O_S}(r_1(z) \cdots r_{\gamma}) \);
      iii. \( \ell_\gamma := \text{GETINDEXOF}_{I_\ell, B_S, O_S}(r_1(z) \cdots r_{\gamma}) \);
      iv. if \( i_0 = 1 \), then \( j := \ell_\gamma \);
      v. if \( 1 < i_0 \leq (m_{\kappa,\eta,d} + 1) \), then \( j := |S| + (i_0 - 2) \cdot (|S| + \text{length}_{RS,=}(\ell, \kappa)) + \ell_\gamma \);
      vi. if \( (m_{\kappa,\eta,d} + 1) < i_0 \leq 2^\eta + 1 \), then \( j := \bot \);
      vii. output \( j \);
   (g) if \( m_{\kappa,\eta,d} \cdot (d_{\kappa,\eta} + 1) < d + 1 \) and \( i_0 \in \{1, \ldots, 1 + 2^\eta\} \), where \( i_0 := i - (m_{\kappa,\eta,d} \cdot \text{query}_{RS,=}(\ell, \kappa) + \text{query}_{RS,<}(\ell, \kappa, d_{\kappa,\eta,d})) \), then:
      i. \( r_1(z) \cdots r_{\gamma} := r_1 \cdots r_{\kappa} \);
      ii. \( \gamma := \text{GETRAND}_{I_\ell, B_S, O_S}(r_1(z) \cdots r_{\gamma}) \);
      iii. \( \ell_\gamma := \text{GETINDEXOF}_{I_\ell, B_S, O_S}(r_1(z) \cdots r_{\gamma}) \);
      iv. if \( i_0 = 1 \), then \( j := \ell_\gamma \);
      v. if \( 1 < i_0 \leq (m_{\kappa,\eta,d} + 1) \), then \( j := |S| + (i_0 - 2) \cdot (|S| + \text{length}_{RS,=}(\ell, \kappa)) + \ell_\gamma \);
      vi. if \( i = m_{\kappa,\eta,d} + 2 \), then \( j := |S| + m_{\kappa,\eta,d} \cdot (|S| + \text{length}_{RS,=}(\ell, \kappa)) + \ell_\gamma \);
      vii. if \( (m_{\kappa,\eta,d} + 2) < i_0 \leq 2^\eta + 1 \), then \( j := \bot \);
      viii. output \( j \).

The corresponding algorithm \( D_{RS,>} \) is defined as follows:

\[
D_{RS,>}((I_\ell, B_S, O_S, d), r_1 \cdots r_{\text{rand}_{RS,=}(\ell, \kappa, d)}, \alpha_1 \cdots \alpha_{\text{query}_{RS,=}(\ell, \kappa, d)}) \equiv \\
1. \text{If } d \geq 2^k, \text{ then output } 1. \\
2. \text{If } d < 2^k, \text{ then:}
\]
11.3.4 Non-Adaptivity of the explicit input of $\Pr$.

Lemma 11.19. $\Pi$ is a non-adaptive (strong) PCPP verifier.

Proof. The explicit input of $\Pi$ is $\langle I, B, S, d \rangle$, where $I$ is an irreducible polynomial over $\mathbb{F}_2$ of degree $\ell$ with root $x$, which induces the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$, $B = (a_1, \ldots, a_n)$ and $S$ is a basis and offset of a $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$, and $d$ is a positive integer; the implicit input of $\Pi$ is a function $p: S \to \mathbb{F}_{2^\ell}$. (For more details on the algorithm $\Pi$, see Algorithm 13.) The proof of proximity $\pi$ of $\Pi$ is parsed according to whether $d$ is less than, equal to, or greater than $d_{\kappa, n} := |S|/2^n - 1 = 2^{k-n} - 1$; see Algorithm 4 for the algorithm that computes the proof of proximity according to these three cases. Finally, see Lemma C.4 for $\query_{\Pi}(\ell, \kappa, d)$, $\rand_{\Pi}(\ell, \kappa, d)$, and $\text{length}_{\Pi}(\ell, \kappa, d)$.

The correctness of both $Q_{\Pi}$ and $D_{\Pi}$ easily follows by inspection of the algorithms and the above discussion, as well as Lemma 11.16 and Lemma 11.17. \hfill \Box

11.3.4 Non-Adaptivity of $V_{\Pi}$

Lemma 11.19. $V_{\Pi}$ is a non-adaptive (strong) PCPP verifier.

Proof. The explicit input of $V_{\Pi}$ is $\langle I, B, S, d \rangle$, where $I$ is an irreducible polynomial over $\mathbb{F}_2$ of degree $\ell$ with root $x$, which induces the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$, $B = (a_1, \ldots, a_n)$ and $S$ is a basis and offset of a $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$, and $d$ is a positive integer; the implicit input of $V_{\Pi}$ is a function $p: S \to \mathbb{F}_{2^\ell}$. (For more details on the algorithm $V_{\Pi}$, see Algorithm 13.) The proof of proximity $\pi$ of $V_{\Pi}$ is parsed according to whether $d$ is less than, equal to, or greater than $d_{\kappa, n} := |S|/2^n - 1 = 2^{k-n} - 1$; see Algorithm 4 for the algorithm that computes the proof of proximity according to these three cases. Finally, see Lemma C.4 for $\query_{\Pi}(\ell, \kappa, d)$, $\rand_{\Pi}(\ell, \kappa, d)$, and $\text{length}_{\Pi}(\ell, \kappa, d)$.

78
The algorithm $V_{RS}$ simply calls $V_{RS,<}$, $V_{RS,=}$, or $V_{RS,>}$ according to the three cases for $d$ with respect to $d_{\kappa,\eta}$. (Unless $\kappa \leq \eta$, in which case $V_{RS}$ directly tests the degree.) The algorithms for $Q_{RS}$ and $D_{RS}$ therefore follow immediately.

Thus, the algorithm $Q_{RS}$ is defined as follows:

$$Q_{RS}\left((I_\ell, \mathcal{B}_S, \mathcal{O}_S, d), r_1 \cdots r_{\text{rand}_{RS}(\ell,\kappa,d)}, i\right) \equiv$$

1. If $\kappa \leq \eta$:
   (a) Output $j := i$.
2. If $\kappa > \eta$:
   (a) Set $d_{\kappa,\eta} := |S|/2^n - 1$.
   (b) If $d < d_{\kappa,\eta}$, then output $j := Q_{RS,<}\left((I_\ell, \mathcal{B}_S, \mathcal{O}_S, d), r_1 \cdots r_{\text{rand}_{RS,<}(\ell,\kappa,d)}, i\right)$.
   (c) If $d = d_{\kappa,\eta}$, then output $j := Q_{RS,=}\left((I_\ell, \mathcal{B}_S, \mathcal{O}_S), r_1 \cdots r_{\text{rand}_{RS,=}(\ell,\kappa), i}\right)$.
   (d) If $d > d_{\kappa,\eta}$, then output $j := Q_{RS,>}\left((I_\ell, \mathcal{B}_S, \mathcal{O}_S, d), r_1 \cdots r_{\text{rand}_{RS,>}(\ell,\kappa,d), i}\right)$.

The corresponding algorithm $D_{RS}$ is defined as follows:

$$D_{RS}\left((I_\ell, \mathcal{B}_S, \mathcal{O}_S, d), r_1 \cdots r_{\text{rand}_{RS}(\ell,\kappa,d)}, \alpha_1 \cdots \alpha_{\text{query}_{RS}(\ell,\kappa,d)}\right) \equiv$$

1. If $\kappa \leq \eta$:
   (a) $P := \text{SUBSPACEINTERP}(I_\ell, \mathcal{B}_S, \mathcal{O}_S, (\alpha_1, \ldots, \alpha_2^n))$
   (b) $\tilde{d} := \text{deg}(P)$
   (c) if $\tilde{d} \leq d$, output 1, else output 0
2. If $\kappa > \eta$:
   (a) Set $d_{\kappa,\eta} := |S|/2^n - 1$.
   (b) If $d < d_{\kappa,\eta}$, then output $b := D_{RS,<}\left((I_\ell, \mathcal{B}_S, \mathcal{O}_S, d), r_1 \cdots r_{\text{rand}_{RS,<}(\ell,\kappa,d)}, \alpha_1 \cdots \alpha_{\text{query}_{RS,<}(\ell,\kappa,d)}\right)$.
   (c) If $d = d_{\kappa,\eta}$, then output $b := D_{RS,=}\left((I_\ell, \mathcal{B}_S, \mathcal{O}_S), r_1 \cdots r_{\text{rand}_{RS,=}(\ell,\kappa), \alpha_1 \cdots \alpha_{\text{query}_{RS,=}(\ell,\kappa)}\right)$.
   (d) If $d > d_{\kappa,\eta}$, then output $b := D_{RS,>}\left((I_\ell, \mathcal{B}_S, \mathcal{O}_S, d), r_1 \cdots r_{\text{rand}_{RS,>}(\ell,\kappa,d), \alpha_1 \cdots \alpha_{\text{query}_{RS,>}(\ell,\kappa,d)}\right)$.

The correctness of both $Q_{RS}$ and $D_{RS}$ easily follows by inspection of the algorithms and the above discussion, as well as Lemma 11.16, Lemma 11.17, and Lemma 11.18.

**11.3.5 Non-Adaptivity of $V_{RS}$**

**Lemma 11.20.** $V_{RS}$ is a non-adaptive (strong) PCPP verifier.

**Proof.** The explicit input of $V_{RS}$ is $(I_\ell, B_S, O_S, B_H, O_H, d)$, where $I_\ell$ is an irreducible polynomial over $\mathbb{F}_2$ of degree $\ell$ with root $x$, which induces the field extension $F_{2^\ell} := \mathbb{F}_2(x)$, $B_S = (a_1, \ldots, a_\kappa)$ and $O_S$ are a basis and offset of a $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$, $B_H = (b_1, \ldots, b_\lambda)$ and $O_H$ are a basis and offset of a $\lambda$-dimensional affine subspace $H \subseteq \mathbb{F}_{2^\ell}$, and $d$ is a positive integer; the implicit input of $V_{RS}$ is a function $p : S \rightarrow \mathbb{F}_{2^\ell}$. (For more details on the algorithm $V_{RS}$, see Algorithm 12.) The proof of proximity $\pi$ of $V_{RS}$ is parsed as a pair $(\tilde{p}, \tilde{\pi})$ where $\tilde{\pi}$ is a proof of proximity for the function $\tilde{p}$ to $RS(\mathbb{F}_{2^\ell}, S, d - |H|)$; see Algorithm 3 for the algorithm that computes the proof of proximity. Finally, see Lemma C.5 for $\text{query}_{V_{RS}}(\ell, \kappa, \lambda, d)$, $\text{rand}_{V_{RS}}(\ell, \kappa, \lambda, d)$, and $\text{length}_{V_{RS}}(\ell, \kappa, \lambda, d)$.

The algorithm $V_{RS}$ simply calls $V_{RS}$ on input $(I_\ell, B_S, O_S, d - |H|)$ (using the proximity proof $\pi = (\tilde{p}, \tilde{\pi})$ as the pair of oracles for $V_{RS}$), then makes two queries (one to the implicit input $p$, and one to the function $\tilde{p}$ in the proximity proof $\pi$), and performs a consistency test between the functions $p$ and $\tilde{p}$.

Thus, the algorithm $Q_{V_{RS}}$ is defined as follows:
\( Q_{\text{VRS}} \left( (I, B_S, O_S, B_H, O_H, d), r_1 \cdots r_{\text{rand}_{\text{VRS}}(\ell, \kappa, d)} \right) \equiv \\

1. If \( i \in \{1, \ldots, \text{query}_{\text{RS}}(\ell, \kappa, d)\} \), then:
   (a) \( r_1^{(a)} \cdots r_{\kappa}^{(a)} := r_1 \cdots r_{\kappa} \);
   (b) \( j_{\text{old}} := Q_{\text{RS}}((I, B_S, O_S, d - |H|), r_1^{(a)} \cdots r_{\kappa}^{(a)}); \)
   (c) \( j := |S| + j_{\text{old}}; \)
   (d) output \( j \).
2. If \( i = \text{query}_{\text{RS}}(\ell, \kappa, d) + 1 \), then:
   (a) \( r_1^{(a)} \cdots r_{\kappa}^{(a)} := r_1 \cdots r_{\kappa} \);
   (b) \( \alpha := \text{GetRandELT}(I, B_S, O_S; r_1^{(a)} \cdots r_{\kappa}^{(a)}); \)
   (c) \( j_{\text{old}} := \text{GetIndexOfELT}(I, B_S, O_S, \alpha); \)
   (d) \( j := j_{\text{old}}; \)
   (e) output \( j \).
3. If \( i = \text{query}_{\text{RS}}(\ell, \kappa, d) + 2 \), then:
   (a) \( r_1^{(a)} \cdots r_{\kappa}^{(a)} := r_1 \cdots r_{\kappa} \);
   (b) \( \alpha := \text{GetRandELT}(I, B_S, O_S; r_1^{(a)} \cdots r_{\kappa}^{(a)}); \)
   (c) \( j_{\text{old}} := \text{GetIndexOfELT}(I, B_S, O_S, \alpha); \)
   (d) \( j := |S| + j_{\text{old}}; \)
   (e) output \( j \).

The corresponding algorithm \( D_{\text{VRS}} \) is defined as follows:

\[ D_{\text{VRS}} \left( (I, B_S, O_S, B_H, O_H, d), r_1 \cdots r_{\text{rand}_{\text{VRS}}(\ell, \kappa, d)}, \alpha_1 \cdots \alpha_{\text{query}_{\text{VRS}}(\ell, \kappa, \lambda, d)} \right) \equiv \\

1. Parse \( \alpha_1 \cdots \alpha_{\text{query}_{\text{VRS}}(\ell, \kappa, \lambda, d)} \) as \( \alpha_1 \cdots \alpha_{\text{query}_{\text{VRS}}(\ell, \kappa, d - |H|)} \alpha \).
2. \( r_1^{(a)} \cdots r_{\kappa}^{(a)} := r_1 \cdots r_{\kappa} \).
3. \( b_{\text{RS}} := D_{\text{RS}}((I, B_S, O_S, d - |H|), r_1^{(a)} \cdots r_{\kappa}^{(a)}); \)
4. \( r_1^{(a)} \cdots r_{\kappa}^{(a)} := r_1 \cdots r_{\kappa} \).
5. \( \alpha := \text{GetRandELT}(I, B_S, O_S; r_1^{(a)} \cdots r_{\kappa}^{(a)}). \)
6. \( [Z_H]^\lambda := \text{FindSubspPoly}(I, B_H, O_H); \)
7. \( \tau := [Z_H]^\lambda(\alpha); \)
8. If \( (\omega = \tau \cdot \tilde{\omega}) \), then \( b_{\text{consist}} := 1 \) else \( b_{\text{consist}} := 0. \)
9. \( b := b_{\text{RS}} \land b_{\text{consist}}. \)
10. Output \( b \).

The correctness of both \( Q_{\text{VRS}} \) and \( D_{\text{VRS}} \) easily follows by inspection of the algorithms and the above discussion, as well as Lemma 11.19. \( \Box \)

11.3.6 Non-Adaptivity of \( V_{\text{RS}} \)

**Lemma 11.21.** \( V_{\text{RS}} \) is a non-adaptive PCPP verifier.

**Proof.** The algorithm \( V_{\text{RS}} \) is (as the name suggests) an algorithm that amplifies the soundness of \( V_{\text{RS}} \); we let \( \text{SN}(\delta, n) \) denote the soundness function of \( V_{\text{RS}} \). With the exception of the addition of the proximity parameter \( \delta \) and target constant soundness \( s' \in [0, 1] \), \( V_{\text{RS}} \) has the same explicit input, implicit input, and proof of proximity structure as \( V_{\text{RS}} \); all of these were briefly recalled in Lemma 11.19. For more details on the algorithm \( V_{\text{RS}} \), see Algorithm 11. (Note that there is
no prover algorithm that is “specialized” for \( V_{aRS} \), because its corresponding prover is the same as the one for \( V_{RS} \); more details on the prover for \( V_{RS} \) can be found in Algorithm 4.) Finally, see Lemma C.6 for \( \text{query}_{aRS}(\ell, \kappa, d, \delta, s') \) and \( \text{rand}_{aRS}(\ell, \kappa, d, \delta, s') \).

The algorithm \( V_{RS} \) simply calls \( V_{RS} \) several times, on the same input but with different randomness, and then accepts if and only if all the calls to \( V_{RS} \) accept. Hence, the algorithms \( Q_{aRS} \) and \( D_{aRS} \) for \( V_{RS} \) can easily be constructed using the algorithms \( Q_{RS} \) and \( D_{RS} \) for \( V_{RS} \).

Specifically, the algorithm \( Q_{aRS} \) is defined as follows:

\[
Q_{aRS}\left((I_l, B_S, O_S, d, \delta, s'), r_1 \cdots r_{\text{rand}_{aRS}(\ell, \kappa, d, \delta, s')}, i\right) \equiv
\]

1. \( m := \left\lceil \frac{\log(1-s')}{\log(1-2^{\ell, \kappa, d, \delta, s'})} \right\rceil \).
2. Let \( z \in \{1, \ldots, m\} \) be such that \( i \in \{(z-1)\cdot\text{query}_{RS}(\ell, \kappa, d) + 1, \ldots, z\cdot\text{query}_{RS}(\ell, \kappa, d)\} \).
3. \( i_{\text{new}} := i - (z - 1) \cdot \text{query}_{RS}(\ell, \kappa, d) \).
4. \( r_1^{(i_{\text{new}})} \cdots r_{(i_{\text{new}})}^{(i_{\text{new}})} \text{rand}_{RS}(\ell, \kappa, d) := r_{(i_{\text{new}}-1)}^{(i_{\text{new}}-1)} \cdot \text{rand}_{RS}(\ell, \kappa, d) + 1 \cdots r_{i_{\text{new}}}^{i_{\text{new}}} \cdot \text{rand}_{RS}(\ell, \kappa, d) \).
5. \( j := Q_{RS}\left((I_l, B_S, O_S, d), r_1^{(i_{\text{new}})} \cdots r_{(i_{\text{new}})}^{(i_{\text{new}})} \text{rand}_{RS}(\ell, \kappa, d), i_{\text{new}}\right) \).
6. Output \( j \).

The corresponding algorithm \( D_{aRS} \) is defined as follows:

\[
D_{aRS}\left((I_l, B_S, O_S, d, \delta, s'), r_1 \cdots r_{\text{rand}_{aRS}(\ell, \kappa, d, \delta, s')}, \alpha_1 \cdots \alpha_{\text{query}_{aRS}(\ell, \kappa, d, \delta, s')}\right) \equiv
\]

1. \( m := \left\lceil \frac{\log(1-s')}{\log(1-2^{\ell, \kappa, d, \delta, s'})} \right\rceil \).
2. Parse \( \alpha_1 \cdots \alpha_{\text{query}_{aRS}(\ell, \kappa, d, \delta, s')} \) as \( \alpha_1^{(1)} \cdots \alpha_1^{(m)} \cdots \alpha_m \).
3. For \( i = 1, \ldots, m \), do the following:
   (a) \( r_1^{(i)} \cdots r_{(i)}^{(i)} \text{rand}_{RS}(\ell, \kappa, d) := r_{(i-1)}^{(i-1)} \cdot \text{rand}_{RS}(\ell, \kappa, d) + 1 \cdots r_i^{(i)} \cdot \text{rand}_{RS}(\ell, \kappa, d) \);
   (b) \( b_i := D_{RS}\left((I_l, B_S, O_S, d), r_1^{(i)} \cdots r_{(i)}^{(i)} \text{rand}_{RS}(\ell, \kappa, d), \alpha_1^{(i)} \cdots \alpha_m^{(i)} \text{query}_{RS}(\ell, \kappa, d)\right) \).
4. \( b := b_1 \land \cdots \land b_m \).
5. Output \( b \).

The correctness of both \( Q_{aRS} \) and \( D_{aRS} \) easily follows by inspection of the algorithms and the above discussion, as well as Lemma 11.19.

Note that, in our explicit description of the algorithm \( V_{RS} \) (from Algorithm 11), we have chosen to not worry about randomness efficiency, so that each run of the sequential repetition is performed using fresh randomness; this is in contrast to the randomness-efficient result given for this step in [BSS08, Proposition 2.9]. Of course, as was mentioned before (see Remark 10.2), the reason is that a randomness-efficient sampler would complicate the construction unnecessarily, given that in this work we are not worried about randomness efficiency. Of course, if one wanted to consider a randomness-efficient \( V_{aRS} \), one could easily modify the above algorithms \( Q_{aRS} \) and \( D_{aRS} \) to account for that, by simply changing how the two algorithms give randomness to each sequential run.

11.3.7 Non-Adaptivity of \( V_{AVRS} \)

**Lemma 11.22.** \( V_{AVRS} \) is a non-adaptive PCPP verifier.
Proof. This proof is completely analogous to that of Lemma 11.21, but, for completeness, we write it in full. The algorithm $V_{\text{aVRS}}$ is (as the name suggests) an algorithm that amplifies the soundness of $V_{\text{RS}}$: we let $s_{\text{aVRS}}(\delta, n)$ denote the soundness function of $V_{\text{RS}}$. With the exception of the addition of the proximity parameter $\delta$ and the target soundness $s'$, $V_{\text{aVRS}}$ has the same explicit input, implicit input, and proof of proximity structure as $V_{\text{RS}}$: all of these were briefly recalled in Lemma 11.20. For more details on the algorithm $V_{\text{aVRS}}$, see Algorithm 10. (Note that there is no prover algorithm that is “specialized” for $V_{\text{aVRS}}$, because its corresponding prover is the same as the one for $V_{\text{RS}}$: more details on the prover for $V_{\text{RS}}$ can be found in Algorithm 3.) Finally, see Lemma C.7 for $\text{query}_{\text{aVRS}}(\ell, \kappa, \lambda, d, \delta, s')$ and $\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d, \delta, s')$.

The algorithm $V_{\text{aVRS}}$ simply calls $V_{\text{RS}}$ several times, on the same input but with different randomness, and then accepts if and only if all the calls to $V_{\text{RS}}$ accept. Hence, the algorithms $Q_{\text{aVRS}}$ and $D_{\text{aVRS}}$ for $V_{\text{aVRS}}$ can easily be constructed using the algorithms $Q_{\text{RS}}$ and $D_{\text{RS}}$ for $V_{\text{RS}}$.

Specifically, the algorithm $Q_{\text{aVRS}}$ is defined as follows:

$$Q_{\text{aVRS}}((I_t, B_S, O_S, B_H, O_H, d, \delta, s'), r_1 \cdots r_{\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d, \delta, s')}, i) \equiv$$

1. $m := \left\lceil \frac{\log(1-s')}{{\log(1-\text{aVRS}(\delta, 2^n))}} \right\rceil$.
2. Let $z \in \{1, \ldots, m\}$ be such that $i \in \{1, \ldots, \text{query}_{\text{aVRS}}(\ell, \kappa, \lambda, d) + 1, \ldots, z \cdot \text{query}_{\text{aVRS}}(\ell, \kappa, \lambda, d)\}$.
3. $i_{\text{new}} := i - z \cdot \text{query}_{\text{RS}}(\ell, \kappa, \lambda, d)$.
4. $r_1^{(i_{\text{new}})} \cdots r_{\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d)}^{(i_{\text{new}})} := r_1^{(i_{\text{new}}-1)} \cdots r_{\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d)}^{(i_{\text{new}}-1)} \cdots r_{\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d)}^{(i_{\text{new}})}$.
5. $j := Q_{\text{RS}}((I_t, B_S, O_S, B_H, O_H, d), r_1^{(i_{\text{new}})} \cdots r_{\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d)}^{(i_{\text{new}})}, i_{\text{new}})$.
6. Output $j$.

The corresponding algorithm $D_{\text{aVRS}}$ is defined as follows:

$$D_{\text{aVRS}}((I_t, B_S, O_S, B_H, O_H, d, \delta, s'), r_1 \cdots r_{\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d, \delta, s')}, \alpha_1 \cdots \alpha_{\text{query}_{\text{aVRS}}(\ell, \kappa, \lambda, d, \delta, s')} \equiv$$

1. $m := \left\lceil \frac{\log(1-s')}{{\log(1-\text{aVRS}(\delta, 2^n))}} \right\rceil$.
2. Parse $\alpha_1 \cdots \alpha_{\text{query}_{\text{aVRS}}(\ell, \kappa, \lambda, d, \delta, s')}$ as $\alpha_1^{(1)} \cdots \alpha_1^{(m)} \cdots \alpha_1^{(m)}$.
3. For $i = 1, \ldots, m$, do the following:
   (a) $r_1^{(i)} \cdots r_{\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d)}^{(i)} := r_1^{(i-1)} \cdots r_{\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d)}^{(i-1)} \cdots r_{\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d)}^{(i)}$.
   (b) $b_i := D_{\text{RS}}((I_t, B_S, O_S, B_H, O_H, d), r_1^{(i)} \cdots r_{\text{rand}_{\text{aVRS}}(\ell, \kappa, \lambda, d)}^{(i)}, \alpha_1^{(i)} \cdots \alpha_{\text{query}_{\text{aVRS}}(\ell, \kappa, \lambda, d)}^{(i)})$.
4. $b := b_1 \wedge \cdots \wedge b_m$.
5. Output $b$.

The correctness of both $Q_{\text{aVRS}}$ and $D_{\text{aVRS}}$ easily follows by inspection of the algorithms and the above discussion, as well as Lemma 11.20. 

11.3.8 Non-Adaptivity of $V_{\text{sACSP}}$

Lemma 11.23. $V_{\text{sACSP}}$ is a non-adaptive PCP verifier.

Proof. The PCP verifier $V_{\text{sACSP}}$ is given as input an instance $(x, 1')$, allegedly in $\text{sACSP}$, and oracle access to a PCP proof $\pi$. (For more details on the algorithm $V_{\text{sACSP}}$, see Algorithm 9.) The PCP proof $\pi$ is parsed as a tuple $(p_0, p_0, p_1, p_1, p_\varepsilon)$ where $p_0$ is a proof of proximity for $p_0$.
to $RS(\mathbb{F}_t, \mathbb{F}_t, 2^{m_H(t)} - 1)$, $\pi_1$ is a proof of proximity for $p_1$ to $VRS(\mathbb{F}_t, \mathbb{F}_t, H_t, d)$, and $\pi_c$ is a proof of proximity for $p_0 - p_x$ to $VRS(\mathbb{F}_t, \mathbb{F}_t, I_{log|x|}, 2^{m_H(t)} - 1)$ for a certain degree $d$, function $p_x$, and affine subspace $I_{log|x|}$; see Algorithm 2 for the algorithm that computes the PCP proof. Finally, see Lemma C.8 for $query_{ACSP}(x, t)$, $rand_{ACSP}(x, t)$, and $length_{ACSP}(x, t)$.

The algorithm $V_{ACSP}$ consists of five main steps: in the first step, $V_{ACSP}$ generates the necessary “objects” needed for running subsequent steps; in the second step, $V_{ACSP}$ tests proximity of $p_0$ to $RS$ (using a specific proximity parameter $\delta_{RS}$ and target soundness $s_{RS} = 1/2$); in the third step, $V_{ACSP}$ tests proximity of $p_1$ to $VRS$ (using another specific proximity parameter $\delta_{VRS}$ and target soundness $s_{VRS} = 1/2$); in the fourth step, $V_{ACSP}$ runs a consistency test between $p_0$ and $p_1$; in the fifth step, $V_{ACSP}$ tests proximity of $p_0 - p_x$ to $VRS$ (using another specific proximity parameter $\delta_c$ and target soundness $s_{c} = 1/2$).

The algorithm $Q_{ACSP}$ is then easily defined as follows:

\[
Q_{ACSP}(\langle x, 1^t \rangle, r_1 \cdots r_{\text{rand}_{ACSP}(x, t)} : \bar{i}) \equiv \\
\]

1. Parameter instantiation:
   (a) $I_t := \text{FindIRRPoly}(1^t(t))$;
   (b) $B_{F_t} := \text{FIELDBasis}(I_t)$;
   (c) $(B_{H_t}, O_{H_t}) := \text{FindH}(1^t)$;
   (d) for $i = 1, \ldots, c_N(t)$, $[N_{t,i}]^a := \text{FindN}(1^i, i)$;
   (e) $[P_i]^a := \text{FindP}(1^i)$;
   (f) $(B_{I_{log|x|}}, O_{I_{log|x|}}) := \text{FindI}(1^t, 1^{log|x|})$;
   (g) $d := \text{deg}(P(x, x; 2^{m_H(t)} - 1) \cdot \text{deg}(N_{t,i}), \ldots, x; (2^{m_H(t)} - 1) \cdot \text{deg}(N_{t,c_N(t)}))$.

2. Deduce the amount of randomness and number of queries for the amplified verifiers:
   (a) $\delta_{RS} := (8 \sum_{i \in \mathbb{F}_t} \text{deg}(N_{t,i}))^{-1}$ and $s'_{RS} := 0.5$;
   (b) $n_{q_{RS}} := \text{query}_{RS}(f(t), f(t), 2^{m_H(t)} - 1, \delta_{RS}, s'_{RS})$;
   (c) $n_{r_{RS}} := \text{rand}_{RS}(f(t), f(t), 2^{m_H(t)} - 1, \delta_{RS}, s'_{RS})$;
   (d) $\delta_{VRS} := \frac{1}{2}$ and $s'_{VRS} := 0.5$;
   (e) $n_{q_{VRS}} := \text{query}_{VRS}(f(t), f(t), m_H(t), d, \delta_{VRS}, s'_{VRS})$;
   (f) $n_{r_{VRS}} := \text{rand}_{VRS}(f(t), f(t), m_H(t), d, \delta_{VRS}, s'_{VRS})$;
   (g) $\delta_{c} := (8 \sum_{i \in \mathbb{F}_t} \text{deg}(N_{t,i}))^{-1}$ and $s'_{c} := 0.5$;
   (h) $n_{q_{c}} := \text{query}_{c}(f(t), f(t), \text{log}|x|, 2^{m_H(t)} - 1, \delta_{c}, s'_{c})$;
   (i) $n_{r_{c}} := \text{rand}_{c}(f(t), f(t), \text{log}|x|, 2^{m_H(t)} - 1, \delta_{c}, s'_{c})$.

3. If $i \in \{1, \ldots, n_{q_{RS}}\}$, then:
   (a) $r'_{1} \cdots r'_{n_{q_{RS}}} := r_1 \cdots r_{n_{q_{RS}}}$;
   (b) $j_{old} := Q_{RS}(\langle I_t, B_{F_t}, 0_{F_t}, 2^{m_H(t)} - 1, \delta_{RS}, s'_{RS}, r'_{1} \cdots r'_{n_{q_{RS}}} : i \rangle)$;
   (c) $j := j_{old}$;
   (d) output $j$.

4. If $i_{new} \in \{1, \ldots, n_{q_{VRS}}\}$, where $i_{new} := i - n_{q_{RS}}$, then:
   (a) $r''_{1} \cdots r''_{n_{q_{VRS}}} := r_1 \cdots r_{n_{q_{VRS}}}$;
   (b) $j_{old} := Q_{VRS}(\langle I_t, B_{F_t}, 0_{F_t}, B_{H_t}, O_{H_t}, d, \delta_{VRS}, s'_{VRS}, r''_{1} \cdots r''_{n_{q_{VRS}}}, i_{new} \rangle)$;
   (c) $j := 2^t(f(t) + length_{RS}(f(t), f(t), 2^{m_H(t)} - 1, \delta_{RS}, s'_{RS}) + j_{old})$;
   (d) output $j$.

5. If $i_{new} \in \{1, \ldots, c_N(t) + 1\}$, where $i_{new} := i - n_{q_{RS}} - n_{q_{VRS}}$, then:
   (a) $r^{(a)}_{1} \cdots r^{(a)}_{f(t)} := r_1 \cdots r_{f(t)}$;
   (b) $\alpha := \text{GetRandELT}(I_t, B_{F_t}, 0_{F_t}, r^{(a)}_{1} \cdots r^{(a)}_{f(t)})$;
The corresponding algorithm \( D_{\text{ACSP}} \) is defined as follows:

\[
D_{\text{ACSP}}(\{x, 1\}^t, r_1 \cdots r_{\text{rand}_{\text{ACSP}}}(x, t), \alpha_1 \cdots \alpha_{\text{query}_{\text{ACSP}}}(x, t)) \equiv \\
1. \text{Parameter instantiation:} \\
   (a) \quad L := \text{FindIRrPOLY}(1^{f(t)}); \\
   (b) \quad B_{F_t} := \text{FIELDBASIS}(L_t); \\
   (c) \quad (B_{H_t}, \mathcal{O}_{H_t}) := \text{FindH}(1^t); \\
   (d) \quad \text{for } i = 1, \ldots, c_N(t), [N_{t,i}]^A := \text{FindN}(1^i, i); \\
   (e) \quad [P_i]^1 := \text{FindP}(1^t); \\
   (f) \quad (B_{t, \log |x|}, \mathcal{O}_{t, \log |x|}) := \text{FindI}(1^t, 1^{\log |x|}); \\
   (g) \quad d := \deg(P(x, x^{(2^{m_H(t)}-1)\deg(N_{t,1})}, \ldots, x^{(2^{m_H(t)}-1)\deg(N_{t,c_N(t)})})).
\]

2. \text{Reduce the amount of randomness and number of queries for the amplified verifiers:}

   (a) \quad \delta_{\text{RS}} := \left(8 \sum_{i=1}^{c_N(t)} \deg(N_{t,i})\right)/1 - s'_{\text{RS}} = 0.5; \\
   (b) \quad \text{nq}_{\text{ARS}} := \text{query}_{\text{ARS}}(f(t), f(t), 2^{m_H(t)} - 1, \delta_{\text{RS}}, s'_{\text{RS}}); \\
   (c) \quad \text{nq}_{\text{ARS}} := \text{rand}_{\text{ARS}}(f(t), f(t), 2^{m_H(t)} - 1, \delta_{\text{RS}}, s'_{\text{RS}}); \\
   (d) \quad \delta_{\text{RS}} := 1/2 \text{ and } s'_{\text{RS}} := 0.5; \\
   (e) \quad \text{nc}_{\text{ARS}} := \text{query}_{\text{ARS}}(f(t), f(t), m_H(t), d, \delta_{\text{RS}}, s'_{\text{RS}}); \\
   (f) \quad \text{nc}_{\text{ARS}} := \text{rand}_{\text{ARS}}(f(t), f(t), m_H(t), d, \delta_{\text{RS}}, s'_{\text{RS}}); \\
   (g) \quad \delta_{\text{RS}} := \left(8 \sum_{i=1}^{c_N(t)} \deg(N_{t,i})\right)/1 - s'_{\text{RS}} = 0.5; \\
   (h) \quad \text{nc}_{\text{ARS}} := \text{query}_{\text{ARS}}(f(t), f(t), m_H(t) - 1, \delta_{\text{RS}}, s'_{\text{RS}}); \\
   (i) \quad \text{nc}_{\text{ARS}} := \text{rand}_{\text{ARS}}(f(t), f(t), m_H(t) - 1, \delta_{\text{RS}}, s'_{\text{RS}}).

3. \text{Parse } \alpha_1 \cdots \alpha_{\text{query}_{\text{ACSP}}}(x, t) \text{ as}

\[
\alpha_1 \cdots \alpha_{\text{nc}_{\text{ARS}}} \alpha_1' \cdots \alpha_{\text{nc}_{\text{ARS}}} \gamma_1 \cdots \gamma_{c_N(t)} \omega t_1 \cdots t_{\text{nc}_{t}}. 
\]

4. \( r_1' \cdots r_{\text{nc}_{\text{ARS}}} := r_1 \cdots r_{\text{nc}_{\text{ARS}}}. 
\]
5. \( b_{\text{RS}} := D_{\text{ARS}}(L_t, B_{F_t}, 0_{F_t}, 2^{m_H(t)} - 1, \delta_{\text{RS}}, s'_{\text{RS}}, r_1' \cdots r_{\text{nc}_{\text{ARS}}}, \alpha_1' \cdots \alpha_{\text{nc}_{\text{ARS}}}). 
\]
6. \( r_1'' \cdots r_{\text{nc}_{\text{ARS}}} := r_1 \cdots r_{\text{nc}_{\text{ARS}}}. 
\]
7. \( b_{\text{VRS}} := D_{\text{VRS}}((I_t, B_{\text{F}}, 0_{\text{F}}, B_{H_t}, O_{H_t}, d, \delta_{\text{VRS}}, s'_{\text{VRS}}), r''_{1}, \ldots, r''_{r_{n_{\text{VRS}}}}, \alpha''_{1}, \ldots, \alpha''_{nq_{\text{VRS}}}). \)

8. \( r_{1}^{(\alpha)} \cdots r_{f_{1}}^{(\alpha)} := r_1 \cdots r_{f_{1}}. \)

9. \( \alpha := \text{GetRandEl}t(I_t, B_{\text{F}}, 0_{\text{F}}, r_{1}^{(\alpha)} \cdots r_{f_{1}}^{(\alpha)}). \)

10. \([P_{1}]^\alpha := \text{FindP}(1').\)

11. \( \omega' := [P_{1}]^{\alpha}(\alpha, \gamma_1, \ldots, \gamma_{\text{CN}(t)}). \)

12. \( b_{\text{P}} := (\omega' = \omega). \)

13. \( r''_{1} \cdots r''_{m_{\text{e}}} := r_{1} \cdots r_{m_{\text{e}}}. \)

14. \( b_{\text{c}} := D_{\text{VRS}}((I_t, B_{\text{F}}, 0_{\text{F}}, B_{I_{1},\log[s]}, O_{I_{1},\log[s]}, 2^{m_{\text{H}}(t)} - 1, \delta_{c}, s'_{c}, r''_{1} \cdots r''_{m_{\text{e}}}, 1 \cdots r_{n_{\text{q}}}). \)

15. \( b := b_{\text{RS}} \land b_{\text{VRS}} \land b_{\text{P}} \land b_{\text{c}}. \)

16. Output \( b. \)

The correctness of both \( Q_{\text{ACSP}} \) and \( D_{\text{ACSP}} \) easily follows by inspection of the algorithms and the above discussion, as well as Lemma 11.21 and Lemma 11.22.

### 11.4 Efficient Reverse Sampling

The third property considered by Barak and Goldreich [BG08, Definition 3.2, third item] for a PCP verifier is the ability to efficiently find a random string that is consistent with a given query:

**Definition 11.24** (Efficient Reverse Sampling). A PCP (resp., PCPP) verifier \( V \) is efficiently reverse samplable if \( V \) is a non-adaptive PCP (resp., PCPP) verifier, and hence can be decomposed into the pair of algorithms \( Q \) and \( D \), and, moreover, there exists a probabilistic polynomial-time algorithm \( S \) such that, given any string \( x \) and positive integers \( i \) and \( j \), \( S(x, i, j) \) outputs a uniformly distributed string \( r \) that satisfies \( Q(x, r, i) = j \).

We prove that the PCP verifier \( V_{\text{ACSP}} \) does satisfy the definition above — that this is so is not clear, especially in light of the recursive nature of \( V_{\text{RS},=1} \) used as part of the construction of \( V_{\text{ACSP}}. \)

**Claim 11.25.** The PCP verifier \( V_{\text{ACSP}} \) is efficiently reverse samplable.

Again, the construction of \( V_{\text{ACSP}} \) is quite complicated, and we will have to proceed one step at a time. As before, our proof will be “bottom up”. Please refer to Figure 1 for an algorithmic reference of the construction of \( V_{\text{ACSP}}. \) (More specific references will be given in each of the proofs.) Also, as we did in Section 11.3, we fix throughout a specific choice of parameters \((\eta, \kappa_0, \gamma, \mu)\), which parametrize \( V_{\text{ACSP}}. \)

Throughout, the symbol \( \circ \) will denote string concatenation.

### 11.4.1 Efficient Reverse Sampling of \( V_{\text{RS},=} \)

**Lemma 11.26.** The (strong) PCPP verifier \( V_{\text{RS},=} \) is efficiently reverse-samplable.

**Proof.** Recall the definitions from Lemma C.1. We have already established in Lemma 11.16 that \( V_{\text{RS},=} \) is a non-adaptive (strong) PCPP verifier. We are left to construct the probabilistic polynomial-time “reverse sampler”: on input \((I_t, B_{L}, O_{L})\), a query number \( i \in \{1, \ldots, \text{query}_{\text{RS},=}((\ell, \kappa))\}\), and a query index \( j \in \{1, \ldots, |L| + \text{length}_{\text{RS},=}((\ell, \kappa))\}\),

\[
S_{\text{RS},=}((I_t, B_{L}, O_{L}), i, j) \equiv \]
1. Compute \((r, n, t) := \text{RANDSAMP}((I_t, B_L, O_L), i, j))\).

2. Output \(r\).

Similarly to \(Q_{\text{RS}, \cdot}\), we have exported the “hard work” of \(S_{\text{RS}, \cdot}\) to an iterative procedure, \text{RANDSAMP} passing more state; on input an irreducible polynomial \(I_t\) of degree \(\ell\) with root \(x\), a basis \(B_L\) and offset \(O_L\) for a \(\kappa\)-dimensional affine subspace \(L \subseteq \mathbb{F}_{2^\ell}\), a query number \(i \in \{1, \ldots, \text{query}_{\text{RS}, \cdot}(\ell, \kappa)\}\), and a query index \(j \in \{1, \ldots, |L| + \text{length}_{\text{RS}, \cdot}(\ell, \kappa)\}\), the procedure \text{RANDSAMP} outputs a triple \((r, n, t)\), where \(r \in \{0, 1\}^{\text{rand}_{\text{RS}, \cdot}(\ell, \kappa)}\) is a uniformly distributed string satisfying \(j = Q_{\text{RS}, \cdot}((I_t, B_L, O_L), r, i)\), \(n\) is the cardinality of all such strings \(r\), and 

\[ t = \text{rand}_{\text{RS}, \cdot}(\ell, \kappa). \]

Essentially, deducing the algorithm \text{RANDSAMP} amounts to carefully examining the algorithm \text{TRANSLATE}, which was the iterative procedure doing the “hard work” of \(Q_{\text{RS}, \cdot}\), on known inputs \(I_t, B_L, O_L\), and \(i\) but without knowing the input randomness \(r\); of course (and this is the point), we do know that the output is (text,elt,j), for some text and elt, and the goal of \text{RANDSAMP} is to find a string \(r\) that is consistent with the known inputs and output and, moreover, is in fact uniformly distributed among all such strings; it will be convenient to also keep track of the numbers \(n\) and \(t\) described in the previous paragraph.

At high level, the algorithm \text{RANDSAMP} will act differently, depending on whether the query \(j\) under consideration is to the implicit input \(p\): \(L \rightarrow \mathbb{F}_{2^\ell}\) or to the proximity proof \(\pi = (f, \Pi)\); in the former case, \(j\) must be between 1 and \(|L| = 2^\kappa\), while, in the latter case, \(j \in \{0, 1\}^{\text{length}_{\text{RS}, \cdot}(\ell, \kappa)}\) must be between 1 and \(|L| + |L| + \text{length}_{\text{RS}, \cdot}(\ell, \kappa)\); \(\gamma = \frac{1}{\ell} + \mu\). In fact, if the query \(j\) is to the proximity proof, \text{RANDSAMP} will also distinguish between the case that \(j\) is a query to \(f\), a query to one of the row-test proofs of proximity, and a query to one of the column-test proofs of proximity. We now describe the algorithm \text{RANDSAMP} in detail:

\text{RANDSAMP}((I_t, B_L, O_L), i, j) \equiv

1. if \(\kappa \leq \kappa_0\), then output \((\varepsilon, 0, 0)\).

2. if \(\kappa > \kappa_0\), then do the following:

   \(a\) \(m_0 := \lceil \kappa/2 \rceil + \gamma, \quad m_1 := \lceil \kappa/2 \rceil - \gamma + \mu;\)

   \(b\) \(m := 1 + \max\{m_0, m_1\};\)

   \(c\) \(B_{L_0} := (a_1, \ldots, a_{\lceil \kappa/2 \rceil - \gamma};) \cup O_{L_0} := O_L;\)

   \(d\) \(B_{L_0} := (a_1, \ldots, a_{\lceil \kappa/2 \rceil - \gamma + \mu};) \cup O_{L_0} := O_L;\)

   \(e\) \(B_{L_0} := (a_{\lceil \kappa/2 \rceil - \gamma}, \ldots, a_\kappa); \cup O_{L_0} := O_L;\)

   \(f\) \([Z_{L_0}]^m := \text{FINDSUBSPOLY}(I_t, B_{L_0}, O_{L_0});\)

   \(g\) \([Z_{L_0}]^{m_1} := ([Z_{L_0}]^m(a_{\lceil \kappa/2 \rceil - \gamma + 1}) + \ldots, [Z_{L_0}]^m(a_\kappa) + [Z_{L_0}]^m(0_{\mathbb{F}_\ell}));\)

   \(h\) if \(j' \in \{1, \ldots, 2^\kappa\}\), where \(j' := j\), then do the following:

     \(i\) \(\alpha := \text{GETELTWITHINDEX}(I_t, B_{L_0}, O_{L_0}, j');\)

     \(ii\) \(\beta \in (1, \ldots, \text{length}_{\text{RS}, \cdot}(\ell, \kappa)) \cup \text{O}_L;\)

     \(iii\) if \(\beta \in \text{L}_0\), then \(B_{L_0} := (a_1, \ldots, a_{\lceil \kappa/2 \rceil - \gamma + \mu};) \cup O_{L_0};\)

     \(iv\) if \(\beta \notin \text{L}_0\), then \(B_{L_0} := (a_{\lceil \kappa/2 \rceil - \gamma + \mu};) \cup O_{L_0};\)

     \(v\) \(O_{L_0} := O_{L_0};\)

     \(vi\) if \(\alpha \notin \text{L}_0\), then do the following:

       \(A\) \(r_1 := 0;\)

       \(B\) \(r_2 \cdots r_{1+m_0} := \text{GERANDFROMELT}(I_t, B_{L_1}, O_{L_1}, \beta);\)

       \(C\) \(\tilde{m}_0 := m_1 - m_0;\)
D. if \( \tilde{m} > 0 \), draw \( r_{m-\tilde{m_0}+1}, \ldots, r_m \in \{0, 1\} \) at random;
E. \( j'' := \text{INDEXOFELT}(I_r, B_{L_0}, O_{L_0}, \alpha) \);
F. \((\tau_0, n_0, \ell_0) := \text{RANDSAMP}((I_r, B_{L_0}, O_{L_0}), i, j'')\);
G. output \((r_1 \cdots r_m \circ \tau_0, 2^{\tilde{m_0}} \cdot n_0, 2^m \cdot \ell_0)\);

vii. if \( \alpha \in L'_0 \), then do the following:

first figure out the probability mass to assign to a row test
A. \( r_2^{(0)} \cdots r_1^{(0)} := \text{GETRANDFROMELT}(I_r, B_{L_1}, O_{L_1}, \beta) \);
B. \( \tilde{m_0} := m - 1 - n_0 \);
C. if \( \tilde{m_0} > 0 \), draw \( r_0^{(0)}, \ldots, r_{m-\tilde{m_0}+1}^{(0)} \in \{0, 1\} \) at random;
D. \( j'' := \text{INDEXOFELT}(I_r, B_{L_0}, O_{L_0}, \alpha) \);
E. \((\tau_0, n_0, \ell_0) := \text{RANDSAMP}((I_r, B_{L_0}, O_{L_0}), i, j'')\);

then figure out probability mass to assign to a column test
F. \( r_1^{(1)} \cdots r_{1+m_1}^{(1)} := \text{GETRANDFROMELT}(I_r, B_{L_0}, O_{L_0}, \alpha) \);
G. \( \tilde{m_1} := m - 1 - n_1 \);
H. if \( \tilde{m_1} > 0 \), draw \( r_0^{(1)}, \ldots, r_{m-\tilde{m_1}+1}^{(1)} \in \{0, 1\} \) at random;
I. \( j'' := \text{INDEXOFELT}(I_r, B_{L_0}, O_{L_0}, \alpha) \);
J. \((\tau_1, n_1, \ell_1) := \text{RANDSAMP}((I_r, B_{L_0}, O_{L_0}), i, j'')\);

finally put everything together
K. \( r_1 \cdots r_m \circ \tau_0, 2^{\tilde{m_0}} \cdot n_0 + 2^{\tilde{m_1}} \cdot n_1, 2^m \cdot \ell_0 + 2^m \cdot \ell_1 \);
L. output \((r_1 \cdots r_m \circ \tau, 2^{\tilde{m_0}} \cdot n_0 + 2^{\tilde{m_1}} \cdot n_1, 2^m \cdot \ell_0 + 2^m \cdot \ell_1)\);

(i) if \( j' \in \{1, \ldots, 2^{k+\gamma+1}\} \), where \( j' := j - 2^k \), then do the following:

i.e., \( j \) is a query into the bivariate evaluation \( f \)

i. \( t_{\text{raw}} := \lfloor j'/2^{k/2+\gamma} \rfloor \);
ii. \( t_{\text{col}} := j' - t_{\text{col}} \cdot 2^{k/2+\gamma} \);
iii. \( \alpha := \text{GETELTWITHINDEX}(I_r, B_{L_0}, O_{L_0}, t_{\text{col}}) \);
iv. \( \beta := \text{GETELTWITHINDEX}(I_r, B_{L_0}(L_1), O_{L_0}(L_1) + t_{\text{row}}) \);

to figure out probability mass to assign to a row test
v. \( r_2^{(0)} \cdots r_{1+m_0}^{(0)} := \text{GETRANDFROMELT}(I_r, B_{L_1}, O_{L_1}, \beta) \);
vi. \( \tilde{m_0} := m - 1 - n_0 \);
vii. if \( \tilde{m_0} > 0 \), draw \( r_0^{(0)}, \ldots, r_{m-\tilde{m_0}+1}^{(0)} \in \{0, 1\} \) at random;

viii. \( j'' := t_{\text{col}} \);
ix. \((\tau_0, n_0, \ell_0) := \text{RANDSAMP}((I_r, B_{L_0}, O_{L_0}), i, j'')\);

then figure out probability mass to assign to a column test
x. \( r_1^{(1)} \cdots r_{1+m_1}^{(1)} := \text{GETRANDFROMELT}(I_r, B_{L_1}, O_{L_1}, \alpha) \);
xii. \( \tilde{m_1} := m - 1 - n_1 \);
xiii. if \( \tilde{m_1} > 0 \), draw \( r_0^{(1)}, \ldots, r_{m-\tilde{m_1}+1}^{(1)} \in \{0, 1\} \) at random;
xiv. \( j'' := t_{\text{row}} \);

xv. \((\tau_1, n_1, \ell_1) := \text{RANDSAMP}((I_r, B_{L_0}, O_{L_0}), i, j'')\);

finally put everything together
xvi. \( r_1 \cdots r_m \circ \tau_0, 2^{\tilde{m_0}} \cdot n_0 + 2^{\tilde{m_1}} \cdot n_1, 2^m \cdot \ell_0 + 2^m \cdot \ell_1 \);

(j) if \( j' \in \{1, \ldots, 2^{k/2+\gamma+1}\} \), where \( j' := \lfloor \frac{j - 2^k - 2^{k+\gamma+1}}{\text{length}_{\text{HS}, 0}(L_1/2^{k/2+\gamma+1})} \rfloor \), then do the following:

i.e., \( j \) is a query into a row proximity sub-proof
The (strong) PCPP verifier

Lemma 11.27. The (strong) PCPP verifier \( V_{RS,<} \) is efficiently reverse-samplable.

i. \( r_1 := 0; \)
ii. \( \beta' := \text{GetEltWithIndex}(I_L, B_{Z_{L_0}(L_1)}, O_{Z_{L_0}(L_1)}, j'); \)
iii. deduce \( \beta \in L_1 \) such that \( [Z_{L_0}]^\alpha(\beta) = \beta' \);
iv. \( r_2 \cdots r_{1+m_0} := \text{GetRandFromElt}(I_L, B_{L_1}, O_{L_1}, \beta); \)
v. \( \bar{m}_0 := m - 1 - m_0; \)
vi. if \( \bar{m}_0 > 0 \), draw \( r_{m-\bar{m}_0+1}, \ldots, r_m \in \{0,1\} \) at random;
vii. \( j'' := \begin{cases} 2^{\lceil \kappa/2 \rceil - \gamma + \mu + 1} \cdot \text{length}_{RS,=} (\ell, \lceil \kappa/2 \rceil - \gamma + \mu + 1), & 1 \leq j' \leq 2^{\lfloor \kappa/2 \rfloor - \gamma + \mu} \\
\end{cases} \)
viii. \( (\tau_0, n_0, \ell_0) := \text{Randsamp}(I_L, B_{O_{L_1}}, i, j''); \)
ix. output \( (r_1 \cdots r_m \circ \tau_0, 2\bar{m}_0 \cdot n_0, 2^{\mu} \cdot \ell_0); \)

(k) if \( j' \in \{1, 2^{\lfloor \kappa/2 \rfloor - \gamma + \mu} \}, \) where \( j' := \left\lfloor \frac{j - 2^{\gamma - 2^\mu + 1} - 2^{\lfloor \kappa/2 \rfloor + \gamma} \cdot \text{length}_{RS,=} (\ell, \lceil \kappa/2 \rceil - \gamma + \mu + 1)}{\text{length}_{RS,=} (\ell, \lceil \kappa/2 \rceil + \mu)} \right\rfloor, \) then do the following:

i.e., \( j \) is a query into a column proximity sub-proof

i. \( r_1 := 1; \)
ii. \( \alpha := \text{GetEltWithIndex}(I_L, B_{L_0}, O_{L_0}, j'); \)
iii. deduce \( \beta \in L_1 \) such that \( [Z_{L_0}]^\alpha(\beta) = [Z_{L_0}]^\alpha(\alpha); \)
iv. \( r_2 \cdots r_{1+m_1} := \text{GetRandFromElt}(I_L, B_{L_0}, O_{L_0}, \alpha); \)
v. \( \bar{m}_1 := m - 1 - m_1; \)
vi. if \( \bar{m}_1 > 0 \), draw \( r_{m-\bar{m}_1+1}, \ldots, r_m \in \{0,1\} \) at random;
vii. \( j'' := \begin{cases} 2^{\lfloor \kappa/2 \rfloor + \mu} - (j - 2^\gamma - 2^{\kappa+\mu+1} - 2^{\lfloor \kappa/2 \rfloor + \gamma} \cdot \text{length}_{RS,=} (\ell, \lceil \kappa/2 \rceil - \gamma + u + 1) - j', & j' \geq 1 \text{ and } j' \leq 2^{\lfloor \kappa/2 \rfloor + \gamma} \\
\end{cases} \)
viii. \( (\tau_1, n_1, \ell_1) := \text{Randsamp}(I_L, B_{Z_{L_0}(L_1)}, O_{Z_{L_0}(L_1)}), i, j''); \)
ix. output \( (r_1 \cdots r_m \circ \tau_1, 2\bar{m}_1 \cdot n_1, 2^{\mu} \cdot \ell_1). \)

Note that \( \text{Randsamp} \) happens to be independent of \( i \). Also recall (cf. Lemma C.10) that

\[
\text{length}_{RS,=} (\ell, \kappa) = 2^{\lfloor \kappa/2 \rfloor + \gamma} \cdot 2^{\lfloor \kappa/2 \rfloor - \gamma + \mu + 1} + 2^{\lfloor \kappa/2 \rfloor + \gamma} \cdot \text{length}_{RS,=} (\ell, \lceil \kappa/2 \rceil - \gamma + \mu + 1) + 2^{\lfloor \kappa/2 \rfloor - \gamma + \mu} \cdot \text{length}_{RS,=} (\ell, \lceil \kappa/2 \rceil + \gamma).
\]

The correctness of \( S_{RS,=} \) follows from the correctness of \( \text{Randsamp} \), which follows by inspection. \( \Box \)

We remark that in Step 2(h)i.ii, Step 2(j)i.iii, and Step 2(k)i.iii, \( \text{Randsamp} \) is required to “invert” the polynomial \( Z_{L_0} \). More precisely, given \( \beta' \in Z_{L_0}(\mathbb{F}_{2^\ell}) \), \( \text{Randsamp} \) needs to compute the unique \( \beta \in L_1 \) such that \( Z_{L_0}(\beta) = \beta' \). Even though \( Z_{L_0} \) is a high-degree polynomial, the same fact that implies the existence of a small arithmetic circuit \( [Z_{L_0}]^\alpha \) for computing \( Z_{L_0} \) (see Algorithm 21) also implies a “sparse” computation for finding \( \beta \). Specifically, because \( Z_{L_0} \) is a linearized polynomial (or, more precisely, a shift of such a polynomial), the map \( Z_{L_0} : \mathbb{F}_{2^\ell} \rightarrow \mathbb{F}_{2^\ell} \) is an affine map. Hence, finding \( \beta \) reduces to finding the unique solution in \( L_1 \) of a \( \dim(L_0) \)-dimensional linear system \( Mx + O = \beta' \) where \( M \) and \( O \) are the matrix and offset induced by the affine map \( Z_{L_0} \). This can be done in time that is polynomial in \( \ell \) and \( \kappa \), and thus \( \beta \) can indeed be found efficiently by \( \text{Randsamp} \).

11.4.2 Efficient Reverse Sampling of \( V_{RS,<} \)

Lemma 11.27. The (strong) PCPP verifier \( V_{RS,<} \) is efficiently reverse-samplable.
Proof. Recall the definitions from Lemma C.2. We have already established in Lemma 11.17 that $V_{RS,<}$ is a non-adaptive (strong) PCPP verifier. We are left to construct the probabilistic polynomial-time “reverse sampler”; on input $(I, B_S, O_S, d)$, $i \in \{1, \ldots, \text{query}_{RS,<}(\ell, \kappa, d)\}$, and $j \in \{1, \ldots, |S| + \text{length}_{RS,<}(\ell, \kappa, d)\}$,

$S_{RS,<}\left((I, B_S, O_S, d), i, j\right) \equiv$

1. If $i \in \{1, \ldots, \text{query}_{RS,<}(\ell, \kappa)\}$, then:
   (a) compute $r := S_{RS,<}\left((I, B_S, O_S), i, j\right)$.
2. If $i' \in \{1, \ldots, \text{query}_{RS,<}(\ell, \kappa)\}$, where $i' := i - \text{query}_{RS,<}(\ell, \kappa)$, then:
   (a) if $j \in \{1, \ldots, |S|\}$, then:
      i. compute $r := S_{RS,<}\left((I, B_S, O_S), i', j\right)$;
   (b) if $j' \in \{|S| + 1, \ldots, |S| + \text{length}_{RS,<}(\ell, \kappa)\}$, where $j' := j - \text{length}_{RS,<}(\ell, \kappa)$, then:
      i. compute $r := S_{RS,<}\left((I, B_S, O_S), i', j'\right)$.
3. Output $r$.

Recall that $\text{rand}_{RS,<}(\ell, \kappa, d) = \text{rand}_{RS,<}(\ell, \kappa)$, and thus $r$ is always of the correct length (and thus there is never a need to pad it with random bits). The correctness of $S_{RS,<}$ easily follows by inspection, as well as from Lemma 11.16.

11.4.3 Efficient Reverse Sampling of $V_{RS,>}$

Lemma 11.28. The (strong) PCPP verifier $V_{RS,>}$ is efficiently reverse-samplable.

Proof. Recall the definitions from Lemma C.3. We have already established in Lemma 11.18 that $V_{RS,>}$ is a non-adaptive (strong) PCPP verifier. We are left to construct the probabilistic polynomial-time “reverse sampler”; on input $(I, B_S, O_S, d)$, $i \in \{1, \ldots, \text{query}_{RS,>}(\ell, \kappa, d)\}$, and $j \in \{1, \ldots, |S| + \text{length}_{RS,>}(\ell, \kappa, d)\}$,

$S_{RS,>}\left((I, B_S, O_S, d), i, j\right) \equiv$

1. If $d \geq 2^\kappa$, then output $\perp$. (Because the decision algorithm $D_{RS,>}$ will accept without examining any query answer, and thus the query algorithm $Q_{RS,>}$ will in this case not make any queries.)
2. If $d < 2^\kappa$, then:
   (a) $d_{\kappa,\eta} := |S|/2^\eta - 1$;
   (b) $m_{\kappa,\eta,d} := \lfloor (d + 1)/(d_{\kappa,\eta} + 1) \rfloor$;
   (c) $d_{\kappa,\eta,d} := d - m_{\kappa,\eta,d} \cdot (d_{\kappa,\eta} + 1)$;
   (d) if $i \in \{1, \ldots, m_{\kappa,\eta,d} \cdot \text{query}_{RS,>}(\ell, \kappa)\}$, then:
      i. $z := \lfloor (i - 1)/\text{query}_{RS,>}(\ell, \kappa) \rfloor$;
      ii. $i_{\text{new}} := i - z \cdot \text{query}_{RS,>}(\ell, \kappa)$;
      iii. $j_{\text{new}} := j - \lfloor |S| + z \cdot (|S| + \text{length}_{RS,>}(\ell, \kappa)) \rfloor$;
      iv. $r := S_{RS,<}\left((I, B_S, O_S, i_{\text{new}}, j_{\text{new}})\right)$;
      v. output $r$;
   (e) if $m_{\kappa,\eta,d} \cdot (d_{\kappa,\eta} + 1) < d + 1$ and $i_{\text{new}} \in \{1, \ldots, \text{query}_{RS,>}(\ell, \kappa, d_{\kappa,\eta,d})\}$, where
      i. $i_{\text{new}} := i - m_{\kappa,\eta,d} \cdot \text{query}_{RS,>}(\ell, \kappa)$, then:
      i. $j_{\text{new}} := j - \lfloor |S| + m_{\kappa,\eta,d} \cdot (|S| + \text{length}_{RS,>}(\ell, \kappa)) \rfloor$;
      ii. $r := S_{RS,<}\left((I, B_S, O_S, d_{\kappa,\eta,d}, i_{\text{new}}, j_{\text{new}})\right)$;
      iii. output $r$;
Proof. Recall the definitions from Lemma C.4. We have already established in Lemma 11.19 that \( V_{rs} \) is a non-adaptive (strong) PCPP verifier. We are left to construct the probabilistic polynomial-time “reverse sampler”: on input \((I_\ell, B_S, O_S, d)\), \(i \in \{1, \ldots, \text{query}_{\text{RS}}(\ell, \kappa, d)\}\), and \(j \in \{1, \ldots, |S| + \text{length}_{\text{RS}}(\ell, \kappa, d)\}\),

\[
S_{\text{RS}}\left((I_\ell, B_S, O_S, d), i, j\right) \equiv \]

Recall that \( \text{rand}_{\text{RS}, >}(\ell, \kappa, d) = \max\{\text{rand}_{\text{RS}, >}(\ell, \kappa), \text{1}_{\kappa, \eta, d} \cdot \text{rand}_{\text{RS}, <}(\ell, \kappa, d, \eta, d)\} \), where \( \text{1}_{\kappa, \eta, d} := \begin{cases} 1 & \text{if } (d + 1) > d_{\kappa, \eta, d} \cdot (d_{\kappa, \eta} + 1) \text{ and } \text{1}_{\kappa, \eta, d} := 0 \text{ otherwise,} \\ \end{cases} \) and thus \( r \) is always of the correct length (and thus there is never a need to pad it with random bits). The correctness of \( S_{\text{RS}, >} \) easily follows by inspection, as well as from Lemma 11.16 and Lemma 11.17. \[\Box\]

11.4.4 Efficient Reverse Sampling of \( V_{rs} \)

Lemma 11.29. The (strong) PCPP verifier \( V_{rs} \) is efficiently reverse-samplable.

Proof. Recall the definitions from Lemma C.4. We have already established in Lemma 11.19 that \( V_{rs} \) is a non-adaptive (strong) PCPP verifier. We are left to construct the probabilistic polynomial-time “reverse sampler”: on input \((I_\ell, B_S, O_S, d)\), \(i \in \{1, \ldots, \text{query}_{\text{RS}}(\ell, \kappa, d)\}\), and \(j \in \{1, \ldots, |S| + \text{length}_{\text{RS}}(\ell, \kappa, d)\}\),

\[
S_{\text{RS}}\left((I_\ell, B_S, O_S, d), i, j\right) \equiv \]

90
1. If $\kappa \leq \eta$:
   (a) Output a random string in $\text{rand}_{RS}(\ell, \kappa, d)$.
2. If $\kappa > \eta$:
   (a) Set $d_{\kappa, \eta} := |S|/2^{\eta} - 1$.
   (b) If $d < d_{\kappa, \eta}$, then output $r := S_{RS,<}(I_{\ell}, B_S, O_S, d, i, j)$.
   (c) If $d = d_{\kappa, \eta}$, then output $r := S_{RS,<}(I_{\ell}, B_S, O_S, i, j)$.
   (d) If $d > d_{\kappa, \eta}$, then output $r := S_{RS,>}(I_{\ell}, B_S, O_S, d, i, j)$.
   (e) Pad $r$ with random bits until it is $\text{rand}_{RS}(\ell, \kappa)$-bits long.
   (f) Output $r$.

The correctness of $S_{RS}$ easily follows by inspection, as well as from Lemma 11.16, Lemma 11.17, and Lemma 11.18.

11.4.5 Efficient Reverse Sampling of $V_{VRS}$

**Lemma 11.30.** The (strong) PCPP verifier $V_{VRS}$ is efficiently reverse-samplable.

**Proof.** Recall the definitions from Lemma C.5. We have already established in Lemma 11.20 that $V_{VRS}$ is a non-adaptive (strong) PCPP verifier. We are left to construct the probabilistic polynomial-time “reverse sampler”: on input $(I_{\ell}, B_S, O_S, B_H, O_H, d)$, $i \in \{1, \ldots, \text{query}_{VRS}(\ell, \kappa, \lambda, d)\}$, and $j \in \{1, \ldots, |S| + \text{length}_{VRS}(\ell, \kappa, \lambda, d)\}$,

$$S_{VRS}((I_{\ell}, B_S, O_S, B_H, O_H, d, i, j)) \equiv$$

1. If $i \in \{1, \ldots, \text{query}_{RS}(\ell, \kappa, \lambda, d - |H|)\}$, then:
   (it must be that $j \in \{|S| + 1, \ldots, |S| + \text{length}_{RS}(\ell, \kappa, \lambda, d - |H|)\}$)
   (a) $i_{\text{new}} := i$;
   (b) $j_{\text{new}} := j - |S|$
   (c) $r := S_{RS}((I_{\ell}, B_S, O_S, d - |H|), i_{\text{new}}, j_{\text{new}})$.
2. If $i = \text{query}_{RS}(\ell, \kappa, \lambda, d - |H|) + 1$, then:
   (it must be that $j \in \{1, \ldots, |S|\}$)
   (a) $j_{\text{new}} := j$;
   (b) $\alpha := \text{GetEltWithIndex}(I_{\ell}, B_S, O_S, j_{\text{new}})$;
   (c) $r := \text{GetRandFromElt}(I_{\ell}, B_S, O_S, \alpha)$.
3. If $i = \text{query}_{RS}(\ell, \kappa, \lambda, d - |H|) + 2$, then:
   (it must be that $j \in \{|S| + 1, \ldots, |S| + |S|\}$)
   (a) $j_{\text{new}} := j - |S|$
   (b) $\alpha := \text{GetEltWithIndex}(I_{\ell}, B_S, O_S, j_{\text{new}})$;
   (c) $r := \text{GetRandFromElt}(I_{\ell}, B_S, O_S, \alpha)$.
4. Pad $r$ with random bits until it is $\text{rand}_{VRS}(\ell, \kappa, \lambda, d)$-bits long.
5. Output $r$.

The correctness of $S_{VRS}$ easily follows by inspection, as well as from Lemma 11.19.

11.4.6 Efficient Reverse Sampling of $V_{ARS}$

**Lemma 11.31.** The PCPP verifier $V_{ARS}$ is efficiently reverse-samplable.
Proof. Recall the definitions from Lemma C.6. We have already established in Lemma 11.21 that $V_{aRS}$ is a non-adaptive PCPP verifier. We are left to construct the probabilistic polynomial-time “reverse sampler”: on input $(I_l, B_S, O_S, d, \delta, s')$, $i \in \{1, \ldots, \text{query}_{aRS}(\ell, \kappa, d, \delta, s')\}$, and $j \in \{1, \ldots, |S| + \text{length}_{aRS}(\ell, \kappa, d, \delta, s')\}$,

$$S_{aRS}((I_l, B_S, O_S, d, \delta, s'), i, j) \equiv$$

1. $m := \left\lfloor \frac{\log(1-s')}{\log(1-a_{RS}(\delta, 2^\kappa))} \right\rfloor$.
2. Let $z \in \{1, \ldots, m\}$ be such that $i \in \{(z-1) \cdot \text{query}_{RS}(\ell, \kappa, d) + 1, \ldots, z \cdot \text{query}_{RS}(\ell, \kappa, d)\}$.
3. $i_{new} := i - (z-1) \cdot \text{query}_{RS}(\ell, \kappa, d)$.
4. $j_{new} := j$.
5. $r_z := S_{RS}((I_l, B_S, O_S, d), i_{new}, j_{new})$.
6. For $l \in \{1, \ldots, m\} - \{z\}$, draw a random $\text{rand}_{RS}(\ell, \kappa, d)$-bit string $r_l$.
7. $r := r_1 \cdots r_m$.
8. Output $r$.

The correctness of $S_{aRS}$ easily follows by inspection, as well as from Lemma 11.19.

\[ \square \]

11.4.7 Efficient Reverse Sampling of $V_{aVRS}$

**Lemma 11.32.** The PCPP verifier $V_{aVRS}$ is efficiently reverse-samplable.

*Proof.* Recall the definitions from Lemma C.7. We have already established in Lemma 11.22 that $V_{aVRS}$ is a non-adaptive PCPP verifier. We are left to construct the probabilistic polynomial-time “reverse sampler”: on input $(I_l, B_S, O_S, B_H, O_H, d, \delta, s')$, $i \in \{1, \ldots, \text{query}_{aVRS}(\ell, \kappa, \lambda, d, \delta, s')\}$, and $j \in \{1, \ldots, |S| + \text{length}_{aVRS}(\ell, \kappa, \lambda, d, \delta, s')\}$,

$$S_{aVRS}((I_l, B_S, O_S, B_H, O_H, d, \delta, s'), i, j) \equiv$$

1. $m := \left\lfloor \frac{\log(1-s')}{\log(1-a_{VRS}(\delta, 2^\kappa))} \right\rfloor$.
2. Let $z \in \{1, \ldots, m\}$ be such that $i \in \{(z-1) \cdot \text{query}_{VRS}(\ell, \kappa, \lambda, d) + 1, \ldots, z \cdot \text{query}_{VRS}(\ell, \kappa, \lambda, d)\}$.
3. $i_{new} := i - (z-1) \cdot \text{query}_{VRS}(\ell, \kappa, \lambda, d)$.
4. $j_{new} := j$.
5. $r_z := S_{VRS}((I_l, B_S, O_S, B_H, O_H, d), i_{new}, j_{new})$.
6. For $l \in \{1, \ldots, m\} - \{z\}$, draw a random $\text{rand}_{VRS}(\ell, \kappa, \lambda)$-bit string $r_l$.
7. $r := r_1 \cdots r_m$.
8. Output $r$.

The correctness of $S_{aVRS}$ easily follows by inspection, as well as from Lemma 11.20.

\[ \square \]

11.4.8 Efficient Reverse Sampling of $V_{aACSP}$

**Lemma 11.33.** The PCP verifier $V_{aACSP}$ is efficiently reverse-samplable.

*Proof.* Recall the definitions from Lemma C.8. We have already established in Lemma 11.23 that $V_{aACSP}$ is a non-adaptive PCP verifier. We are left to construct the probabilistic polynomial-time “reverse sampler”: on input $(x, 1^t)$, $i \in \{1, \ldots, \text{query}_{aACSP}(x, t)\}$, and $j \in \{1, \ldots, \text{length}_{aACSP}(x, t)\}$,

$$S_{aACSP}((x, 1^t), i, j) \equiv$$
1. Parameter instantiation:
   (a) \( I_t := \textsc{FindIRRPoly}(1^{f(t)}) \);
   (b) \( B_{E_t} := \textsc{FieldBasis}(I_t) \);
   (c) \((B_t, \mathcal{O}_t) := \textsc{FindH}(1^{t})\);
   (d) for \( i = 1, \ldots, c_N(t) \), \([N_{i,t}]^A := \textsc{FindN}(1^{t}, i)\);
   (e) \([P_t]^A := \textsc{FindP}(1^{t})\);
   (f) \((B_t, \mathcal{O}_t) := \textsc{FindH}(1^{t}, 1^{\log|x|})\);
   (g) \( d := \deg(P_t(x, x^{2m_{\mathcal{H}}(t)} - 1) - \deg(N_{t,1}) \ldots x^{2m_{\mathcal{H}}(t) - 1} - \deg(N_{t,c_N(t)})\)).

2. Deduce the number of queries for the amplified verifiers:
   (a) \( \delta_{\text{RS}} := (8 \sum_{i=1}^{c_N(t)} \deg(N_{i,t}))^{-1} \text{ and } s'_{\text{RS}} := 0.5\);
   (b) \( n_{\text{ARS}} := \textsc{query}_{\text{ARS}}(f(t), f(t), 2^{m_{\mathcal{H}}(t)} - 1, \delta_{\text{RS}}, s'_{\text{RS}})\);
   (c) \( \delta_{\text{VRS}} := \frac{1}{4} \text{ and } s'_{\text{VRS}} := 0.5\);
   (d) \( n_{\text{VRS}} := \textsc{query}_{\text{VRS}}(f(t), f(t), m_{\mathcal{H}}(t), d, \delta_{\text{VRS}}, s'_{\text{VRS}})\);
   (e) \( \delta := (8 \sum_{i=1}^{c_N(t)} \deg(N_{i,t}))^{-1} \text{ and } s'_{\text{VRS}} := 0.5\);
   (f) \( n_{c} := \textsc{query}_{\text{VRS}}(f(t), f(t), \log |x|, 2^{m_{\mathcal{H}}(t)} - 1, \delta_{s}, s'_{c})\).

3. If \( i \in \{1, \ldots, n_{\text{ARS}}\} \), then:
   (a) \( i_{\text{new}} := i \);
   (b) \( j_{\text{new}} := j \);
   (c) \( r := S_{\text{ARS}}((I_t, B_{E_t}, 0_{E_t}, 2^{m_{\mathcal{H}}(t)} - 1, \delta_{\text{RS}}, s'_{\text{RS}}), i_{\text{new}}, j_{\text{new}})\).

4. If \( i_{\text{new}} \in \{1, \ldots, n_{\text{ARS}}\} \), where \( i_{\text{new}} := i - n_{\text{ARS}} \), then:
   (a) \( j_{\text{new}} := j - 2^{m_{\mathcal{H}}(t)} - \text{length}_{\text{ARS}}(f(t), f(t), 2^{m_{\mathcal{H}}(t)} - 1, \delta_{\text{RS}}, s'_{\text{RS}})\);
   (b) \( r := S_{\text{ARS}}((I_t, B_{E_t}, 0_{E_t}, B_t, \mathcal{O}_t, d, \delta_{\text{VRS}}, s'_{\text{VRS}}), i_{\text{new}}, j_{\text{new}})\).

5. If \( i_{\text{new}} \in \{1, \ldots, c_N(t) + 1\} \), where \( i_{\text{new}} := i - n_{\text{ARS}} - n_{\text{VRS}} \), then:
   (a) if \( i_{\text{new}} \in \{1, \ldots, c_N(t)\} \), then:
      i. \( j_{\text{new}} := j \);
      ii. \( \alpha_{\text{new}} := \textsc{GetElWithIndex}(I_t, B_{E_t}, 0_{E_t}, j_{\text{new}})\);
      iii. find a random solution \( \alpha \) to the equation \( \alpha_{\text{new}} := [N_{t,i_{\text{new}}}]^A(x) \);
      iv. \( r := \textsc{GetRandFromEl}(I_t, B_{E_t}, 0_{E_t}, \alpha)\);
   (b) if \( i_{\text{new}} = c_N(t) + 1 \), then:
      i. \( j_{\text{new}} := j \);
      ii. \( \alpha := \textsc{GetElWithIndex}(I_t, B_{E_t}, 0_{E_t}, j_{\text{new}})\);
      iii. \( r := \textsc{GetRandFromEl}(I_t, B_{E_t}, 0_{E_t}, \alpha)\).

6. If \( i_{\text{new}} \in \{1, \ldots, n_{c}\} \), where \( i_{\text{new}} := i - n_{\text{ARS}} - n_{\text{VRS}} - (c_N(t) + 1) \), then:
   (a) if \( j \in \{1, \ldots, 2^{f(t)}\} \), then:
      i. compute \( r := S_{\text{ARS}}((I_t, B_{E_t}, 0_{E_t}, B_{I_{\log|x|}}, \mathcal{O}_{I_{\log|x|}}, \delta_{c}, s'_{c}), i_{\text{new}}, j_{\text{new}})\);
   (b) if \( j' \in \{2^{f(t)} + 1, \ldots, 2^{f(t)} + \text{length}_{\text{ARS}}(f(t), f(t), \log |x|, 2^{m_{\mathcal{H}}(t)} - 1, \delta_{c}, s'_{c})\} \),
      \( \text{where } j' := j - \text{length}_{\text{ARS}}(f(t), f(t), 2^{m_{\mathcal{H}}(t)} - 1, \delta_{\text{RS}}, s'_{\text{RS}}) \)
      \( - 2^{f(t)} - \text{length}_{\text{ARS}}(f(t), f(t), m_{\mathcal{H}}(t), d, \delta_{\text{VRS}}, s'_{\text{VRS}}) \),
      then:
      i. compute \( r := S_{\text{ARS}}((I_t, B_{E_t}, 0_{E_t}, B_{I_{\log|x|}}, \mathcal{O}_{I_{\log|x|}}, \delta_{c}, s'_{c}), i_{\text{new}}, j')\).

7. Pad \( r \) with random bits until it is \( \textsc{random}(x, l) \)-bits long.

8. Output \( r \).

The correctness of \( S_{\text{ACSP}} \) easily follows by inspection, as well as from Lemma 11.21 and Lemma 11.22. Note that in Step 5(a)iii we have to find a random root of the polynomial \( N_{t,i_{\text{new}}}(x) - \alpha_{i_{\text{new}}} \) over \( \mathbb{F}_{2^{f(t)}} \). This can be done in time poly(\( \deg(N_{t,i_{\text{new}}}) \), \( f(t) \)) by factoring the polynomial (e.g., see the survey of [VZGP01]) and selecting one of the roots at random.

\[ \square \]
11.5 Proof Of Knowledge

The fourth property considered by Barak and Goldreich [BG08, Definition 3.2, third item] for a PCP verifier is a proof-of-knowledge property. We show that the PCP verifier \( V_{\text{ACSP}} \) satisfies a variant of the proof-of-knowledge property considered by Barak and Goldreich. At high-level, the original definition of Barak and Goldreich requires the following: if, on input some string \( x \) and with access to some oracle \( \pi \), the PCP verifier accepts with high enough probability, then \( \pi \) “contains” a witness for \( x \), in the sense that there is an efficient knowledge extractor that, on input \( x \) and with oracle access to \( \pi \), can compute any bit of the witness with high probability. Formally:

**Definition 11.34** (PCP Proof of Knowledge). Fix \( \varepsilon : \mathbb{N} \to [0, 1] \). A PCP verifier \( V \) has the proof-of-knowledge property with error \( \varepsilon \) if there exists a probabilistic polynomial-time oracle machine \( E_{\text{PCP}} \) such that the following holds: for every two strings \( x \) and \( \pi \), if \( \Pr[V^\pi(x) = 1] > \varepsilon(|x|) \) then there exists \( w = w_1 \cdots w_T \) such that \( (x, w) \in R \) and, for \( i = 1, \ldots, T \), \( \Pr[E_{\text{PCP}}^\pi(x, i) = w_i] > 2/3 \).

A weaker definition does not require the knowledge extractor \( E_{\text{PCP}} \) to be an implicit representation of the witness, and instead allows \( E_{\text{PCP}} \) to run in time that is polynomial in the witness length:

**Definition 11.35** (Explicit PCP Proof of Knowledge). Fix \( \varepsilon : \mathbb{N} \to [0, 1] \). A PCP verifier \( V \) has the explicit proof-of-knowledge property with error \( \varepsilon \) if there exists a probabilistic polynomial-time oracle machine \( E_{\text{PCP}} \) such that the following holds: for every two strings \( x \) and \( \pi \), if \( \Pr[V^\pi(x) = 1] > \varepsilon(|x|) \) then there exists \( w = w_1 \cdots w_T \) such that \( (x, w) \in R \) and \( \Pr[E_{\text{PCP}}^\pi(x, 1^T) = w] > 2/3 \).

We prove that \( V_{\text{ACSP}} \) satisfies this weaker definition (and then in Remark 11.37 we explain why it does not satisfy the original one). Later, in Section 11.6, we will show that the weak PCP proof-of-knowledge property still suffices for constructing a variant of universal arguments (with a correspondingly weaker proof of knowledge property), which are still useful for a number of applications.

**Claim 11.36.** The PCP verifier \( V_{\text{ACSP}} \) has the PCP explicit proof-of-knowledge property with error \( \varepsilon(n) = 1/2 \).

**Proof.** The PCP verifier \( V_{\text{ACSP}} \) is described in Construction 7.5 (and then again more succinctly in Algorithm 9). The PCP weak proof-of-knowledge property of \( V_{\text{ACSP}} \) can be deduced by examining the part of the proof of Theorem 7.1 that establishes the soundness property of \( V_{\text{ACSP}} \). Details follow.

Fix an instance \((x, 1^{t})\) and a proof \( \pi = (p_0, \pi_1, p_1, \pi_2) \). Suppose that \( \Pr[V^\pi_{\text{ACSP}}((x, 1^{t})) = 1] > 1/2 \). Let \( I_{t, \log |x|} \) be the \((\log |x|)\)-th affine subspace in \( \overline{I}_t \), \( A_x \) be the low-degree extension of the function \( f_x : I_{t, \log |x|} \to \{0, 1\} \) defined by \( f_x(\alpha_i) := x_i \) where \( \alpha_i \) is the \( i \)-th element in \( I_{t, \log |x|} \), and \( p_x \) the evaluation of \( A_x \) on \( \mathbb{F}_t \). Also let \( d := \deg(P_1(x, x^{(2^{mH(t)}-1)\cdot \deg(N_{t, 1})}, \ldots, x^{(2^{mH(t)}-1)\cdot \deg(N_{t,N(t)})})) \).

It must be that

- \( p_0 \) is \( \delta_{\text{RS}} \)-close to \( \text{RS}(\mathbb{F}_t, E_t, 2^{mH(t)} - 1) \),
- \( p_1 \) is \( \delta_{\text{VRS}} \)-close to \( \text{VRS}(\mathbb{F}_t, E_t, H_t, d) \), and

94
• \( p_0 - p_x \) is \( \delta_c \)-close to \( \text{VRS}(F_t, F_t, I_t, \log |x|, 2^{m_H(t)} - 1) \),

where \( \delta_{\text{RS}} = \delta_c = (8 \sum_{i=1}^{\kappa(t)} \deg(N_{t,i}))^{-1} \) and \( \delta_{\text{RS}} = \frac{1}{8} \). Indeed, if that were not the case, then \( V_{\text{sACSP}}(x, 1^t) \) would have accepted with probability at most 1/2 (due respectively to its first, second, and fourth subtest).

Let \( A : F_t \to F_t \) be the unique polynomial of degree less than \( 2^{m_H(t)} \) whose evaluation table over \( F_t \) is closest to \( p_0 \). Note that \( A \) is unique, because \( 1 - (2^{m_H(t)} - 1)/|F_t| \) is larger than \( 2\delta_{\text{RS}} = (4 \sum_{i=1}^{\kappa(t)} \deg(N_{t,i}))^{-1} \). (See Remark 7.6 and Lemma 4.11.) Furthermore, we can deduce that \( A \) is consistent with the instance \( (x, 1^t) \): \( p_0 - p_x \) is \( (8 \sum_{i=1}^{\kappa(t)} \deg(N_{t,i}))^{-1} \)-close to the evaluation of \( A - A_\pi \) on \( F_t \) and \( (8 \sum_{i=1}^{\kappa(t)} \deg(N_{t,i}))^{-1} \)-close to the code \( \text{VRS}(F_t, F_t, I_t, \log |x|, 2^{m_H(t)} - 1) \); thus, invoking once again the fact that \( 1 - (2^{m_H(t)} - 1)/|F_t| \) is larger than \( (4 \sum_{i=1}^{\kappa(t)} \deg(N_{t,i}))^{-1} \) (and Lemma 4.11) we deduce that the evaluation of \( A - A_\pi \) is in \( \text{VRS}(F_t, F_t, I_t, \log |x|, 2^{m_H(t)} - 1) \).

Let \( B : F_t \to F_t \) be the polynomial defined as \( B(x) := P_t(x, A(N_{t,1}(x)), \ldots, A(N_{t,\kappa(t)}(x))) \).

Because \( p_0 \) is \( (8 \sum_{i=1}^{\kappa(t)} \deg(N_{t,i}))^{-1} \)-close to the evaluation table of \( A \) over \( F_t \), we deduce that, for \( i = 1, \ldots, \kappa(t) \), \( p_0 \circ N_{t,i} \) is \( 8 \sum_{i=1}^{\kappa(t)} \deg(N_{t,i})^{-1} \)-close to the evaluation table of \( A \circ N_{t,i} \).

Define the function \( p_2 : F_t \to F_t \) by

\[
p_2(x) := P_t\left(x, p_0(N_{t,1}(x)), \ldots, p_0(N_{t,\kappa(t)}(x))\right).
\]

We deduce then, via a union bound, that \( p_2 \) must be 1/8-close to the evaluation table of \( B(x) \) over \( F_t \).

Now let \( B' : F_t \to F_t \) be the unique polynomial of degree at most \( d \) vanishing on \( H_t \) whose evaluation table over \( F_t \) is closest to \( p_1 \). Again note that \( B' \) is unique, because \( 1 - d/|F_t| \) is larger than \( 2\delta_{\text{RS}} = 1/4 \). (See Remark 7.6 and Lemma 4.11.) We argue that \( B' \) and \( B \) must be equal. Indeed, suppose by way of contradiction that \( B' \) and \( B' \) are distinct; then, as they are both polynomials of degree at most \( d \leq |F_t|/4 \), their evaluation tables over \( F_t \) may agree on at most a 1/4 fraction of their entries; hence, by a union bound, the third subtest of \( V_{\text{sACSP}} \) accepts with probability at most \( 1/8 + 1/8 + 1/4 \leq 1/2 \) — a contradiction to the fact that \( V_{\text{sACSP}}(x, 1^t) \) accepts with probability greater than 1/2.

Since \( B' \) and \( B \) are equal, \( B \) vanishes on \( H_t \), so that (together with the fact that \( A \) is consistent with the instance \( (x, 1^t) \)) we deduce that \( A \) is a witness to the fact that \( (x, 1^t) \) is \( \text{sACSP} \).

In summary, \( p_0 \) a function over \( F_t \) that is \( (8 \sum_{i=1}^{\kappa(t)} \deg(N_{t,i}))^{-1} \)-close to a (unique) polynomial \( A \) of degree less than \( 2^{m_H(t)} \); moreover \( A \) is a witness to the fact that \( (x, 1^t) \) \( \in \text{sACSP} \).

We can then define \( E_{\text{PCP}} \) as follows:

\[
E_{\text{PCP}}^\pi(x, 1^t) \overset{\text{def}}{=} \\
1. \text{Parse } \pi \text{ as } (p_0, \pi_0, p_1, \pi_1). \\
2. \text{Compute } I_t := \text{FindIrrPoly}(1^{f(t)}). \\
3. \text{Set } B_{F_t} := (1, x, \ldots, x^{f(t)-1}).
\]
4. Set $d := 2^{m_H(t)} - 1$.

5. Compute $A(x) := \text{DECODER}(I_t, \text{span}(B_{2^d}), 1^d, p_0)$.

6. Output $A(x)$.

Note that, similarly to the verifier $V_{sACSP}$, the knowledge extractor $E_{PCP}$ also knows the choice of parameters for $sACSP$; so, for example, it knows the functions $f$ and $m_H(t)$. Clearly, $E_{PCP}$ runs in polynomial time.\footnote{More precisely, $E_{PCP}$ will run in $\text{poly}(2^{m_H(t)})$ time, which is polynomial in $1^{2^d}$ whenever $m_H(t) = t + o(t)$. Indeed, the “true” measure of instance size in $sACSP$ problems is $2^{m_H(t)}$ and not $2^t$.}

Thus, it is easy to see that whenever $V_{sACSP}$ accepts the instance $(x, 1^t)$ and oracle $\pi$ with probability greater than $1/2$, it is indeed the case that $E_{PCP}$ succeeds in extracting a witness with probability greater than $2/3$. (In fact, it succeeds with probability 1.)

Remark 11.37. Even for an “honest” oracle $\pi = (p_0, \pi_0, p_1, \pi_1, \pi_c)$ (e.g., the one produced by the PCP prover $P_{sACSP}$ on input $(x, 1^t)$ and a witness $A$ for $(x, 1^t)$), retrieving $A$ from its error-free evaluation $p_0$ over $\mathbb{F}_t$ requires working at least linearly in $\deg(A)$, which may very well be linear in $2^t$. Indeed, simply reading less than $\deg(A)$ values of $p_0$ is not enough information to uniquely determine $A$. Hence, at least for $V_{sACSP}$ we must settle for a “weak” proof-of-knowledge where if we want to extract a bit of the witness, then we might as well extract the whole witness. Fortunately, as discussed in more detail in Section 11.6, for many applications of universal arguments this is not an issue.

 Remark 11.38. Fix $\kappa \in \mathbb{N}$. If a PCP verifier $V$ has the PCP explicit proof-of-knowledge property with error $\varepsilon$, then the PCP verifier $V$ sequentially repeated $\kappa$ times has the PCP explicit proof-of-knowledge property with error $\varepsilon^\kappa$. (Indeed, whenever the repeated verifier accepts a PCP oracle $\pi$ with probability greater than $2^{\kappa-\varepsilon}$, then the non-repeated verifier must accept the same PCP oracle $\pi$ with greater than half probability.)

Remark 11.39. Barak and Goldreich claimed [BG08, Appendix A] that the PCP proof of knowledge (cf. Definition 11.34) holds for many PCPs, yet the PCPs that we use only satisfy the explicit PCP proof of knowledge (cf. Definition 11.35). The reason is that many PCP constructions (e.g., [BFLS91]) use multivariate techniques, as opposed to univariate techniques as we do. More precisely, many PCP constructions use low-degree low-variate multivariate polynomials when it comes to arithmetizing certain constraint satisfaction problems. With multivariate techniques, the witness is encoded using a Reed-Muller code (via a low-degree extension), which has much better local-decoding properties than Reed-Solomon codes: a witness $w$ of size $2^t$ is mapped to a $d$-degree $m$-variate polynomial with $m = O(t/\log t)$ and $d = O(t)$ and a bit of $w$ can be retrieved in time $\text{poly}(t)$ [BF90, Lip90].

As discussed before, the advantage of univariate techniques over multivariate techniques is that the proof length of the PCP oracle can be made very short; namely, we do not know of PCPs of quasilinear length based on multivariate techniques but we do when based on univariate techniques.

11.6 Obtaining (Almost) Universal Arguments

Having proved that the PCP system $(P_{sACSP}, V_{sACSP})$ for $sACSP$ does satisfy the first three properties and a variant of the fourth property considered by Barak and Goldreich [BG08, Definition 3.2], we now explain how these four properties are enough to imply, through [BG08, Construction 3.4], an almost universal argument system for $sACSP$. (See Definition 11.9.)
Claim 11.40. Following [BG08, Construction 3.4] by starting with the (amplified) PCP system $(P_{sACSP}, V_{sACSP})$ and a collision-resistant hash function yields an almost universal argument system $(P_{UA}, V_{UA})$ for the language $sACSP$.

We assume familiarity with the proof of [BG08, Lemma 3.5], which shows that the construction of universal arguments given in [BG08, Construction 3.4] using a PCP system satisfying the original four properties in [BG08, Definition 3.2] works, as long as a collision-resistant function family is used.

In comparison, our Claim 11.40 says that, even if we start with a PCP system that satisfies a slightly weaker notion of proof of knowledge (i.e., Definition 11.8 instead of Definition 11.6), the construction of universal arguments still yields a universal argument, albeit with a correspondingly weaker notion of proof of knowledge, that is, yields an almost universal argument. (And, of course, the other two properties of efficient verification and completeness via a relatively-efficient prover easily follow from using the same construction [BG08, Construction 3.4].)

As discussed in Remark 11.2, this is sufficient for most “positive” applications, because an almost universal argument is, in particular, also a succinct argument of knowledge for $NP$, and this latter primitive is usually sufficient for applications.

Proof of Claim 11.40. We give a high-level overview of the proof [BG08, Lemma 3.5], and then explain (and give details of) how it can be modified to yield the proof for our claim. Also, in this proof we assume that $V_{sACSP}$ has been amplified to error $2^{-\kappa}$ for inputs of length $\kappa$; in particular, it has the PCP explicit proof-of-knowledge property with error $\varepsilon(\kappa) = 2^{-\kappa}$. (See Remark 11.38.)

Roughly, the argument used to prove [BG08, Lemma 3.5] consists of three steps:

1. First, one shows that, if a prover circuit is too inconsistent about answering queries and yet is still somewhat convincing, then that prover can be efficiently converted into a collision-finding circuit; in particular, that means that, in order to be somewhat convincing, a prover circuit must essentially “have a PCP oracle in mind”.

2. Next, one shows how to construct an efficient “oracle recovery” procedure, i.e., a probabilistic polynomial-time oracle machine recover that, with access to the prover circuit, is an implicit representation of a PCP oracle that is also somewhat convincing (this time convincing to the PCP verifier). This step crucially relies on the existence of an efficient reverse sampler.

3. Finally, one shows how this oracle recovery procedure can be used, together with the PCP knowledge extractor, to yield the knowledge extractor required by the weak proof-of-knowledge property from Definition 11.6.

Even given this high-level overview, it is clear that the first two steps of the argument of Barak and Goldreich work in our case too, because they only rely on the collision-resistant property and the fact that the prover is somewhat convincing. On the other hand, step three (which clearly refers to the PCP knowledge extractor), requires modification. So we now show how to use the oracle recovery procedure together with our knowledge extractor to produce a “weaker” universal-argument knowledge extractor that will satisfy Definition 11.8 instead.

More precisely, we argue as follows. Fix two positive polynomials $s_{UA}$ and $p_{UA}$ and, letting $q_{UA} = 5p_{UA}$, we show how to construct a probabilistic polynomial-time procedure $E_{UA}$ (depending on $s_{UA}$ and $p_{UA}$) such that, for every family of $s_{UA}$-size prover circuits $\tilde{P}_{UA} = \{\tilde{P}_{UA,\kappa}\}_{\kappa \in \mathbb{N}}$, for all
sufficiently large \( \kappa \in \mathbb{N} \), for every instance \((x, 1^t) \in \{0, 1\}^\kappa \), if \( \tilde{P}_{UA, \kappa} \) convinces \( V_{UA} \) to accept \((x, 1^t)\) with probability greater than \( p_{UA}(\kappa)^{-1} \), then, with probability greater than \( q_{UA}(\kappa)^{-1} \) taken over a random choice of internal randomness \( r \) for \( E_{UA} \), the weak knowledge extractor \( E_{UA} \), with oracle access to the code of \( \tilde{P}_{UA, \kappa} \) and on input \((x, 1^t)\), outputs a valid witness \( w \) for \( x \).

Barak and Goldreich [BG08, Claim 3.5.3] showed how to construct a probabilistic polynomial-time oracle machine \( \text{recover} \) (depending on \( s_{UA} \) and \( p_{UA} \)) such that, for all sufficiently large \( \kappa \in \mathbb{N} \), if \( \tilde{P}_{UA, \kappa} \) convinces \( V_{UA} \) to accept \((x, 1^t)\) with probability greater than \( p_{UA}(\kappa)^{-1} \), then, with probability \( \frac{\text{poly}(\kappa)}{\text{poly}(\kappa)} \cdot \text{recover}(\tilde{P}_{UA, \kappa}, (x, 1^t)) \) is an implicit representation of a PCP oracle \( \pi \) such that

\[
\Pr[\forall_{\text{ACSP}}((x, 1^t)) = 1] > \frac{1}{\text{poly}(\kappa)} > \frac{1}{2^{27}}
\]

Also, we amplify the success probability of \( E_{PCP}(x, 1^{2\ell}) \), with \((x, 1^t) \in \{0, 1\}^\kappa \), from greater than 2/3 to greater than 1 – \( 2^{-\kappa} \).

Then, we define the “explicit” weak knowledge extractor \( E_{UA} \) (depending on \( s_{UA} \) and \( p_{UA} \)) as follows: for every family of \( s_{UA} \)-size prover circuits \( \tilde{P}_{UA} = \{\tilde{P}_{UA, \kappa}\}_{\kappa \in \mathbb{N}}, \) for every \( \kappa \in \mathbb{N} \) and instance \((x, 1^t) \in \{0, 1\}^\kappa \),

\[
E_{UA}^{(\tilde{P}_{UA, \kappa})}(x, 1^{2\ell}) \overset{\text{def}}{=} \begin{cases} 
1. \text{Draw a random tape } \omega \text{ for the oracle-recovery procedure } \text{recover}. \\
2. \text{Invoke } E_{PCP}(x, 1^{2\ell}) \text{ providing it with oracle access to } \pi, \text{ using the oracle-recovery procedure } \text{recover} \text{ on input } (x, t), \text{ random tape } \omega, \text{ and oracle access to the code of } \tilde{P}_{UA, \kappa}. \\
3. \text{Output whatever (the amplified) } E_{PCP}^{(x, 1^{2\ell})} \text{ outputs.}
\end{cases}
\]

Note that \( E_{UA} \) does run in polynomial time, because each invocation of \( \text{recover} \) requires \( \text{poly}(\kappa) \) invocations of \( \tilde{P}_{UA, \kappa} \) (for a total of \( \text{poly}(\kappa) \cdot s_{UA}(\kappa) \) time per invocation), and there are at most \( \text{poly}(\|y|, 2^t, \kappa) \) invocations of \( \text{recover}_\varepsilon \) (as the amplified \( E_{PCP} \) runs in \( \text{poly}(|y|, 2^t, \kappa) \) time).

Finally, the probability that \( E_{UA}^{(\tilde{P}_{UA, \kappa})}(x, 1^{2\ell}) \) succeeds in extracting a valid witness for \( y \) is at least the probability that \( \omega \) is a “good” random tape for \( \text{recover}(x, t) \) (i.e., makes it an implicit representation of a “convincing” PCP oracle \( \pi \)) times the probability that \( E_{PCP}^{(x, 1^{2\ell})} \) successfully extracts; for sufficiently large \( \kappa \in \mathbb{N} \), that probability is at least \( \frac{1}{\text{poly}(\kappa)} \cdot (1 - 2^{-\kappa}) > \frac{1}{\text{poly}(\kappa)} \), as desired. \( \Box \)

**Remark 11.41.** Note that the alphabet of the PCP oracle is elements of a finite field \( \mathbb{F}_{2^\ell} \), and not bits. Fortunately, the analysis of the rewinding strategy of the knowledge extractor does not rely on how large the alphabet of the PCP oracle is, but only reasons about consistency of answers across different runs of the prover, and thus the different alphabet does not require any changes in the proof.

---

27 Actually, the oracle-recovery procedure of Barak and Goldreich was constructed to take a randomly chosen collision-resistant function family seed \( \alpha \) as input, but here we include this random choice as part of the procedure.
A Work On Succinct Verification Of Long Computations

While we believe that the question of whether PCPs can be made efficient enough to be used in practice (e.g., via the “commit to a PCP and then reveal” construction [Kil92, Mic00, BG08, DCL08, BCCT11, DFH12, GLR11]) is itself fascinating, a natural question to consider is whether the heavy machinery of PCPs is really needed for the application of succinct verification of long computations.

The answer seems to depend on the strength of the desired application and the strength of the computational assumptions that one is willing to make. Let us explain.

At present, we know that:

- Ishai et al. [IKO07] showed how to use linear PCPs to construct interactive arguments for NP where the prover’s answers are laconic [GH98, GVW02] but where the verifier does not save any time over naive verification of the NP witness.

- Goldwasser et al. [GKR08] showed how to verify log-space uniform NC computations (i.e., log-space uniform circuits of polylogarithmic depth) by relying on probabilistic-checking techniques that are lighter than those used in PCPs; their protocol can be reduced to one round [KR09, KRR12]. Canetti et al. [CRR11] showed how to extend the techniques in [GKR08] to also handle non-uniform NC circuits, in a publicly verifiable one-round protocol having an expensive offline preprocessing phase.

- A set of works [GGP10, CKV10, AIK10] showed how to verify all polynomial-time computations without using probabilistic-checking techniques, provided one is willing to tolerate an expensive offline preprocessing phase.28 (These works, however, deliver a notion of soundness that is not so strong: soundness only holds when the information of whether the verifier has accepted or not remains secret.)

- Groth [Gro10] showed how to construct publicly-verifiable SNARGs of knowledge (SNARKs) for all of NP with an expensive offline preprocessing phase and where both the preprocessing running time and the prover running are quadratic (in the size of the circuit verifying membership in the language). Lipmaa [Lip12] improved on the work of Groth by showing how to make the preprocessing running time quasilinear; however, the prover running time remained quadratic in his work. Gennaro et al. [GGPR12] obtained essentially-optimal time complexities in this setting: both the prover running time and preprocessing running time are quasilinear in their work.

- Bitansky et al. [BCCT12] showed that the expensive preprocessing phase of a SNARK (if there is one) can always be removed via a generic transformation that only relies on standard cryptographic assumptions and does not invoke any probabilistic-checking techniques. Their transformation also shows how to make the prover complexity tightly related in time and space to those of the original computation to be verified.

- Bitansky and Chiesa [BC12] showed how to use multi-prover interactive proof techniques [BOGKW88] to obtain, from standard cryptographic assumptions, interactive succinct arguments where again the prover’s time and space complexities are tightly related to those

28 Though, admittedly, these works rely on the “heavy hammer” of fully-homomorphic encryption [Gen09], which, just like PCPs, is also notoriously inefficient in practice.
of the original computation to be verified; they also showed how to obtain designated-verifier SNARKs, where the prover has similar time and space complexities, from a knowledge assumption about fully-homomorphic encryption.

Thus, it seems that the question of whether full-fledged PCPs are really needed depends on the strength of the desired application (e.g., verify deterministic vs. non-deterministic computations, publicly-verifiable vs. privately-verifiable, interactive vs. non-interactive) and the strength of the computational assumptions we are willing to make (e.g., only falsifiable assumptions or not).

For example, on the one hand, we could make strong non-falsifiable assumptions to only use bilinear techniques and then invoke the result of [BCCT12] to obtain succinct argument constructions that do not invoke “full-fledged” PCPs; on the other hand, we could only assume the existence of collision-resistant hash functions and construct succinct arguments using full-fledged PCPs [Kil92, Mic00, BG08]. Finally, we note that the use of PCPs in constructing succinct arguments is to a certain extent inherent [RV09].

Some of the aforementioned protocols have been optimized and implemented in practice:

- A set of works [SBW11, SMBW12, SVP+12] has optimized and implemented the protocol of Ishai et al. [IKO07]. As mentioned above, the protocol of Ishai et al. is based on the much simpler linear PCPs and not full-fledged PCPs, which are the ones studied in this paper; on the other hand, the protocol of Ishai et al. is only a laconic argument and not a succinct argument (i.e., the prover-to-verifier communication is small but the verifier running time is as expensive as direct verification of the NP witness). Asymptotically, the savings in computation of the verifiers in [SBW11, SMBW12, SVP+12] are thus provided by batching multiple verifications together: in order to verify evaluations of $\ell$ circuits of size $S$, the verifier may run in time $S/\ell$ each. Furthermore, the protocol they obtain is interactive.

- A set of works [CMT12, TRMP12] has optimized and implemented the protocol of Goldwasser et al. [GKR08]. As mentioned above, the protocol of Goldwasser et al. relies on probabilistic-checking techniques that are lighter than those used in full-fledged PCPs; on the other hand, the protocol of Goldwasser et al. (along with the extension by Canetti et al. [CRR11]) can only support verification of deterministic circuits of polylogarithmic depth (as opposed to all non-deterministic polynomial-time computations in PCP-based constructions). We recall that one of the main disadvantages of only supporting deterministic circuits is the lack of fast reductions from random-access machines (cf. [BSCGT12]).

In sum, current implementations are still far from practical succinct verification of all non-deterministic polynomial-time computations. (In fact, at present, there is not even any implementation of a succinct argument for NP! Indeed, both of the above lines of work only support very restricted verification functionalities.)
B PCP Algorithmic Specifications

We provide algorithmic specifications for the PCP system used in the proof of Theorem 1.

The probabilistic-checking core of the PCP system used in the proof of Theorem 1 is the PCP system \((P_{sACSP}, V_{sACSP})\) for the language \(sACSP\) used in the proof of Theorem 7.1 in Section 7; the remaining part of the construction consists instead of Levin reductions.

Recall that a PCP system for the language \(sACSP\) would indeed not be very useful without sufficiently tight Levin reductions from “more natural” languages. Such reductions are studied in detail by Ben-Sasson et al. [BSCGT12], who consider Levin reductions from the correctness of computation of a wide class of random-access machines.

In the algorithmic specifications of this section, we shall thus ignore the details of the specific Levin reduction to \(sACSP\), and only focus on spelling out the details of \((P_{sACSP}, V_{sACSP})\); a complexity analysis of the PCP system’s proof length, randomness, and query complexity is given later in Appendix C.

Concretely, we assume that, for some machine \(M\) of interest, we already know a Levin reduction \((\text{Params}_L, \text{Reduce-Witness}_L, \text{Recover-Witness}_L)\) from the language \(L = \{(x, 1^t) : \text{there is } w \text{ with } |w| \leq 2^t \text{ s.t. } M(x, w) \text{ accepts within } 2^t \text{ steps}\}\) to the language \(sACSP\) with the choice of parameters \(\text{Params}_L\). That is, \(\text{Reduce-Witness}_L\) and \(\text{Recover-Witness}_L\) are polynomial-time computable and the following two properties hold:

1. **Soundness:** \((x, 1^t) \in L \iff (x, 1^t) \in sACSP(\text{Params}_L)\)

2. **Witness Reductions:**

   \[
   \begin{align*}
   &\text{\bullet } w \text{ is witness to } (x, 1^t) \in L \implies \text{Reduce-Witness}_L(w) \text{ is witness to } (x, 1^t) \in sACSP(\text{Params}_L) \\
   &\text{\bullet } \text{Recover-Witness}_L(A) \text{ is witness to } (x, 1^t) \in L \iff A \text{ is witness to } (x, 1^t) \in sACSP(\text{Params}_L)
   \end{align*}
   \]

Note that the input \(x\) itself is not changed by the Levin reduction considered here (i.e., \(L\) is reducible to \(sACSP\) with the choice of parameters \(\text{Params}_L\) via the identity mapping).

In Figure 1 we give a high-level diagram of all the components (together with the dependencies among them) of the PCP system \((P_L, V_L)\) for the language \(L\). Following are pseudocode listings for each component: in Section B.1 are listings for the components of the prover \(P_L\), in Section B.2 are listings for the components of the verifier \(V_L\), and finally in Section B.3 are listings for the finite-field algorithms used throughout.

\[\text{\footnotesize\footnotesize\footnotesize\footnotesize\footnotesize\footnotesize Recall from Definition 6.1 that } sACSP \text{ only considers } (x, 1^t) \text{ such that } |x| \in \{2, \ldots, 2^t\}.\]
Figure 1: A high-level diagram showing the relation among the “modules” in the construction of the PCP prover $P_L$ and PCP verifier $V_L$. Also, every module makes use of certain algorithms for computations in finite fields, which we spell out.
B.1 PCP Prover Specifications

Algorithm 1 $P_L$

**inputs:**
- $(x, 1^t)$, in the language $L$
- $w$, witness to $(x, 1^t) \in L$

**randomness:**
- no randomness used

**output:**
- $\pi$, probabilistically-checkable proof for the satisfiability of $(x, 1^t)$

1. $A \leftarrow \text{Reduce-Witness}_L(w)$
2. $\pi \leftarrow P_{\text{ACSP}}((x, 1^t), A)$
3. output $\pi$

**notes:**
- see Algorithm 8 for $V_L$, the corresponding verifier
- $P_{\text{ACSP}}$ has the choice of parameters $\text{Params}_L$ hardcoded
Algorithm 2 $P_{\text{SACSP}}$

inputs:
- $(x, 1^t)$, in SACSP with the given choice of parameters 
  
  \[ \left( f, (m_\mathbf{H}, t_\mathbf{H}, \mathbf{H}), (c_\mathbf{N}, t_\mathbf{N}, s_\mathbf{N}, \mathbf{N}, (t_p, s_p, p), (t_1, \mathbf{I})) \right) \]

- $A: \mathbb{F}_t \to \mathbb{F}_t$, assignment polynomial that is witness to $(x, t) \in \text{SACSP}$
  (i.e., $\deg(A) < 2^{\mathbf{m}_t(t)}$, $A$ satisfies the constraint polynomial $P_t$, and $A$ is consistent with $(x, 1^t)$, cf. Definition 6.1)

randomness:
- No randomness used

output:
- $\pi = (p_0, \pi_0, p_1, \pi_1, \pi_\epsilon)$, probabilistically-checkable proof for the claim "$(x, 1^t) \in \text{SACSP}$"

1. Parameter instantiation:
   (a) $I_t := \text{FindIrrPoly}(1^{f(t)})$
   (b) $B_{I_t} := \text{FieldBasis}(I_t)$
   (c) $(B_{H_t}, O_{H_t}) := \text{FindH}(1^t)$
   (d) for $i = 1, \ldots, c_\mathbf{N}(t)$, $[N_{i,t}]^\alpha := \text{FindN}(1^t, i)$
   (e) $[P_t]^\alpha := \text{FindP}(1^t)$
   (f) $(B_{I_t, \log \vert x \vert}, O_{I_t, \log \vert x \vert}) := \text{FindI}(1^t, 1^{\log \vert x \vert})$

2. Proof that $A$ has low degree:
   (a) $p_0 := \text{SubspaceEval}(I_t, B_{I_t}, O_{I_t}, A)$
   (b) $\pi_0 := P_{\text{NS}}(I_t, B_{I_t}, O_{I_t}, 2^{\mathbf{m}_t(t)} - 1, A)$

3. Proof that $A$ satisfies the constraint polynomial:
   (a) for each $\alpha \in \mathbb{F}_t$:
      i. use $[P_t]^\alpha$ and $[N_{i,t}]^\alpha$ to compute $\beta := P_t(\alpha, p_0(N_{i,1}(\alpha)), \ldots, p_0(N_{i,c_\mathbf{N}(t)}(\alpha)))$
      ii. set $p_1(\alpha) := \beta$
   (b) $B := \text{SubspaceInterp}(I_t, B_{I_t}, O_{I_t}, p_1)$
   (c) $d := \deg(P_t(x, x^{2^{\mathbf{m}_t(t)} - 1}, \ldots, x^{\deg(N_{i,1})}, \ldots, x^{\deg(N_{i,c_\mathbf{N}(t)})}))$
   (d) $\pi_1 := P_{\text{NS}}(I_t, B_{I_t}, O_{I_t}, d, B)$

4. Proof that $A$ is consistent with $(x, 1^t)$:
   (a) compute $A_x$, the low-degree extension of the function $f_x: I_{t, \log \vert x \vert} \to \{0, 1\}$ defined by 
      \[ f_x(\alpha_i) := x_i \text{ where } \alpha_i \text{ is the } i\text{-th element in } I_{t, \log \vert x \vert} \]
   (b) $\pi_c := P_{\text{NS}}(I_t, B_{I_t}, O_{I_t, \log \vert x \vert}, O_{I_{t, \log \vert x \vert}}, 2^{\mathbf{m}_t(t)} - 1, A - A_x)$
   (c) $\pi := (p_0, \pi_0, p_1, \pi_1, \pi_\epsilon)$

6. Output $\pi$

notes:
- Reference: Construction 7.3
- See Lemma C.8 for complexity bounds on queries and randomness
- See Algorithm 9 for $V_{\text{SACSP}}$, the corresponding verifier
Algorithm 3 $P_{\text{VRS}}$

inputs:
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
- $B_S$ and $O_S$, basis and offset for the $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$
- $B_H$ and $O_H$, basis and offset for the $\lambda$-dimensional affine subspace $H \subseteq \mathbb{F}_{2^\ell}$
- $d$, positive integer indicating what “low-degree” means
- $P : \mathbb{F}_{2^\ell} \to \mathbb{F}_{2^\ell}$, polynomial whose evaluation over $S$ is in $\text{VRS}(\mathbb{F}_{2^\ell}, S, H, d)$

randomness:
- no randomness used

output:
- $\pi = (\tilde{p}, \tilde{\pi})$, proof of proximity to $\text{VRS}(\mathbb{F}_{2^\ell}, S, H, d)$ for the evaluation of $P$ over $S$

1. $\tilde{P} := \text{SubspaceDivide}(I_\ell, B_H, O_H, P)
2. $\tilde{p} := \text{SubspaceEval}(I_\ell, B_S, O_S, \tilde{P})$
3. $\tilde{\pi} := P_{\text{ns}}(I_\ell, B_S, O_S, d - 2^\lambda, \tilde{P})$
4. output $(\tilde{p}, \tilde{\pi})$

notes:
- see Lemma C.5 for complexity bounds on the proof length
- see Algorithm 12 for $V_{\text{VRS}}$, the corresponding verifier
- since the evaluation of $P$ over $S$ is in $\text{VRS}(\mathbb{F}_{2^\ell}, S, H, d)$, it must be that $d \geq |H|$
Algorithm 4 $P_{RS}$

inputs:
- $I_\ell$, irreducible polynomial of degree $\ell$ over $F_2$ with root $x$, inducing the field extension $F_{2^\ell} := F_2(x)$
- $B_S$ and $O_S$, basis and offset for the $\kappa$-dimensional affine subspace $S \subseteq F_{2^\ell}$
- $d$, positive integer indicating what “low-degree” means
- $P : F_{2^\ell} \to F_{2^\ell}$, polynomial whose evaluation over $S$ is in $RS(F_{2^\ell}, S, d)$

randomness:
- no randomness used

output:
- $\pi$, proof of proximity to $RS(F_{2^\ell}, S, d)$ for the evaluation of $P$ over $S$

1. if $\kappa \leq \eta$, then output $\pi := \bot$
2. if $\kappa > \eta$, then:
   (a) $d_{\kappa, \eta} := |S|/2^n - 1 = 2^\kappa/2^n - 1$
   (b) if $d < d_{\kappa, \eta}$, then output $\pi := P_{RS,<}(I_\ell, B_S, O_S, d, P)$
   (c) if $d = d_{\kappa, \eta}$, then output $\pi := P_{RS,=}(I_\ell, B_S, O_S, P)$
   (d) if $d > d_{\kappa, \eta}$, then output $\pi := P_{RS,>}(I_\ell, B_S, O_S, d, P)$

notes:
- see Lemma C.4 for complexity bounds on the proof length
- see Algorithm 13 for $V_{RS}$, the corresponding verifier
- if $\kappa \leq \eta$, then there is no need to output a proximity proof, because $V_{RS}$ will read the entire implicit input to decide whether the implicit input is in $RS(F_{2^\ell}, S, d)$ or not
Algorithm 5 \( P_{\text{RS},>} \)

**inputs:**
- \( I_\ell \), irreducible polynomial of degree \( \ell \) over \( \mathbb{F}_2 \) with root \( x \), inducing the field extension \( \mathbb{F}_{2^\ell} := \mathbb{F}_2(x) \)
- \( B_S \) and \( O_S \), basis and offset for the \( \kappa \)-dimensional affine subspace \( S \subseteq \mathbb{F}_{2^\ell} \)
- \( d \), positive integer, greater than \( |S|/2^\eta - 1 \), indicating what “low-degree” means
- \( P: \mathbb{F}_{2^\ell} \rightarrow \mathbb{F}_{2^\ell} \), polynomial whose evaluation over \( S \) is in \( \text{RS}(\mathbb{F}_{2^\ell}, S, d) \)

**randomness:**
- no randomness used

**output:**
- \( \pi = ((p_0, \pi_0), \ldots, (p_{2^{\eta}-1}, \pi_{2^{\eta}-1})) \), proof of proximity to \( \text{RS}(\mathbb{F}_{2^\ell}, S, d) \) for the evaluation of \( P \) over \( S \)

1. if \( d \geq |S| \), then output \( \pi := \perp \)
2. if \( d < |S| \), then:
   a. \( d_{\kappa,\eta} := |S|/2^\eta - 1 = 2^\kappa/2^\eta - 1 \)
   b. \( m_{\kappa,\eta,d} := [(d+1)/(d_{\kappa,\eta} + 1)] \)
      (note that \( m_{\kappa,\eta,d} \in \{0, \ldots, 2^\eta\} \), because \( 2^\eta \cdot (d_{\kappa,\eta} + 1) = |S| \))
   c. \( P_{\text{rest}}(x) := P(x) \)
   d. for \( i = 0, \ldots, m_{\kappa,\eta,d} - 1 \):
      i. \( P_i(x) := P_{\text{rest}}(x) \mod x^{d_{\kappa,\eta}+1} \)
      ii. \( p_i := \text{SubspaceEval}(I_\ell, B_S, O_S, P_i) \)
      iii. \( \pi_i := P_{\text{RS},>}(I_\ell, B_S, O_S, P_i) \)
      iv. \( P_{\text{rest}}(x) := (P_{\text{rest}}(x) - P_i(x))/x^{d_{\kappa,\eta}+1} \)
   e. \( h := m_{\kappa,\eta,d} \cdot (d_{\kappa,\eta} + 1) \)
   f. if \( h < d + 1 \), then:
      i. \( P_{m_{\kappa,\eta,d}}(x) := P_{\text{rest}} \)
      ii. \( p_{m_{\kappa,\eta,d}} := \text{SubspaceEval}(I_\ell, B_S, O_S, P_{m_{\kappa,\eta,d}}) \)
      iii. \( \pi_{m_{\kappa,\eta,d}} := P_{\text{RS},<}(I_\ell, B_S, O_S, d - h, P_{m_{\kappa,\eta,d}}) \)
3. \( \pi := ((p_0, \pi_0), \ldots, (p_{2^{\eta}-1}, \pi_{2^{\eta}-1})) \)
   (any \( p_i \) or \( \pi_i \) that was not assigned is set to \( \perp \))
4. output \( \pi \)

**notes:**
- see Lemma C.3 for complexity bounds on the proof length
- see Algorithm 14 for \( V_{\text{RS},>} \), the corresponding verifier
- if \( d \geq |S| \), every function \( p: S \rightarrow \mathbb{F}_{2^\ell} \) is in \( \text{RS}(\mathbb{F}_{2^\ell}, S, d) \) (cf. Step 1)
Algorithm 6 \( P_{RS,<} \)

**inputs:**
- \( I_\ell \), irreducible polynomial of degree \( \ell \) over \( \mathbb{F}_2 \) with root \( x \), inducing the field extension \( \mathbb{F}_{2^\ell} := \mathbb{F}_2(x) \)
- \( B_S \) and \( O_S \), basis and offset for the \( \kappa \)-dimensional affine subspace \( S \subseteq \mathbb{F}_{2^\ell} \)
- \( d \), positive integer, less than \( |S|/2^\eta - 1 \), indicating what “low-degree” means
- \( P : \mathbb{F}_{2^\ell} \rightarrow \mathbb{F}_{2^\ell} \), polynomial whose evaluation over \( S \) is in \( RS(\mathbb{F}_{2^\ell}, S, d) \)

**randomness:**
- no randomness used

**output:**
- \( \pi = (\pi_1, \pi_2) \), proof of proximity to \( RS(\mathbb{F}_{2^\ell}, S, d) \) for the evaluation of \( P \) over \( S \)

1. \( d_{\kappa, \eta} := |S|/2^\eta - 1 = 2^\kappa/2^\eta - 1 \)
2. \( Q(x) := x^{d_{\kappa, \eta} - d} \in \mathbb{F}_{2^\ell}[x] \)
3. \( P'(x) := P(x) \cdot Q(x) \)
4. \( \pi_1 := P_{RS,<}(I_\ell, B_S, O_S, P) \)
5. \( \pi_2 := P_{RS,<}(I_\ell, B_S, O_S, P') \)
6. \( \pi := (\pi_1, \pi_2) \)
7. output \( \pi \)

**notes:**
- see Lemma C.2 for complexity bounds on the proof length
- see Algorithm 15 for \( V_{RS,<} \), the corresponding verifier
Algorithm 7 \( P_{RS,=} \)

**inputs:**
- \( I_\ell \), irreducible polynomial of degree \( \ell \) over \( \mathbb{F}_2 \) with root \( x \), inducing the field extension \( \mathbb{F}_{2^\ell} := \mathbb{F}_2(x) \)
- \( B_\ell = (a_1, \ldots, a_\kappa) \) and \( O_L \), basis and offset for the \( \kappa \)-dimensional affine subspace \( L \subseteq \mathbb{F}_{2^\ell} \)
- \( P : \mathbb{F}_{2^\ell} \to \mathbb{F}_{2^\ell} \), polynomial whose evaluation over \( L \) is in \( RS(\mathbb{F}_{2^\ell}, L, |L|/2^{n} - 1) \)

**randomness:**
- no randomness used

**output:**
- \( \pi = (f, \Pi) \), proof of proximity to \( RS(\mathbb{F}_{2^\ell}, L, |L|/2^{n} - 1) \) for the evaluation of \( P \) over \( S \)

1. if \( \kappa \leq \kappa_0 \), then output \( \pi := \perp \)
2. if \( \kappa > \kappa_0 \), then:
   (a) \( B_{L_0} := (a_1, \ldots, a_{\kappa/2} - \gamma) \), \( O_{L_0} := O_L \)
   (b) \( [Z_{L_0}]^\kappa := \text{FindSubpoly}(I_\ell, B_{L_0}, O_{L_0}) \)
   (c) \( B_{L_0} := (a_1, \ldots, a_{\kappa/2}, \gamma - \mu) \), \( O_{L_0} := O_L \)
   (d) \( B_{L_1} := (a_{\kappa/2}, \mu - \gamma + 1, \ldots, a_\kappa) \), \( O_{L_1} := O_L \)
   (e) \( B_{Z_{L_0},(L_1)} := ([Z_{L_0}]^\kappa (a_{\kappa/2} - \gamma + 1) + [Z_{L_0}]^\kappa (0_{\mathbb{F}_{2^\ell}}), \ldots, [Z_{L_0}]^\kappa (a_\kappa) + [Z_{L_0}]^\kappa (0_{\mathbb{F}_{2^\ell}})) \)
   \( O_{Z_{L_0}(L_1)} := [Z_{L_0}]^\kappa (O_{L_1}) \)
   (f) \( L_0 := \text{span}(B_{L_0}) + O_{L_0} \)
   (g) \( L_0 := \text{span}(B_{L_0'}) + O_{L_0'} \)
   (h) \( L_1 := \text{span}(B_{L_1}) + O_{L_1} \)
   (i) for each \( \beta \in L_1 \):
      i. \( O_{L_\beta} := O_{L_\beta} \)
      ii. if \( \beta \in L_0 \), then:
         A. \( B_{L_\beta} := \text{append } a_{\kappa/2} - \gamma + \mu + 1 \text{ to the basis } B_{L_\beta} \)
         B. \( L_\beta := \text{span}(B_{L_\beta}) + O_{L_\beta} = L_0 \cup (L_0 + a_{\kappa/2} - \gamma + \mu + 1 + O_{L_0}) \)
      else:
         A. \( B_{L_\beta} := \text{append } \beta \text{ to the basis } B_{L_\beta} \)
         B. \( L_\beta := \text{span}(B_{L_\beta}) + O_{L_\beta} = L_0 \cup (L_0 + \beta) \)
   (j) \( Q := \text{FindBivariate}(I_\ell, B_{L_0}, O_{L_0}, P) \)
   (k) evaluate \( Q(x, y) = P_0(x) + P_1(x)y + \cdots + P_\ell(x) y^\ell \) on \( \cup_{\beta \in L_1} L_\beta \times \{Z_{L_0}(\beta)\} \) to get \( f \):
      i. for \( t = 0, \ldots, \ell \), \( s_t := \text{SubspaceEval}(I_\ell, B_{Z_{L_0}(L_1)}, O_{Z_{L_0}(L_1)}, P_1) \)
      ii. for each \( \beta \in L_1 \), \( \beta' := [Z_{L_0}]^\kappa (\beta) \) and \( f(\beta, \beta') := \text{SubspaceEval}(I_\ell, B_{L_0}, O_{L_0}, P_\beta) \), where \( P_\beta(y) := s_0(\beta') + s_1(\beta') y + \cdots + s_\ell(\beta') y^\ell \)
   (l) for each \( \beta \in L_1 \):
      i. \( \beta' := [Z_{L_0}]^\kappa (\beta) \)
      ii. \( F_\beta(x) := Q(x, \beta') \)
      iii. \( \pi_{\beta'}^\alpha := P_{\text{hs,=}}(I_\ell, B_{L_0}, O_{L_0}, F_\beta) \)
   (m) for each \( \alpha \in L_0' \):
      i. \( F_{\alpha}(y) := Q(\alpha, y) \)
      ii. \( \pi_{\alpha}^\beta := P_{\text{hs,=}}(I_\ell, B_{Z_{L_0}(L_1)}, O_{Z_{L_0}(L_1)}, F_{\alpha}) \)
   (n) \( \Pi := \{ \pi_{\beta'}^\alpha : \beta' \in Z_{L_0}(L_1) \} \cup \{ \pi_{\alpha}^\beta : \alpha \in L_0' \} \)
   (o) \( \pi := (f, \Pi) \)
   (p) output \( \pi \)

**notes:**
- see Theorem 10.3 for how the parameters \((\eta, \kappa_0, \gamma, \mu)\) can be chosen
- see Lemma C.1 for complexity bounds on the proof length
- see Algorithm 16 for \( V_{\text{hs,=}^a} \), the corresponding verifier
- in Step 2g, some computation can be saved since \( L_0' = L_0 + (\text{span}(a_{\kappa/2} - \gamma + 1, \ldots, a_{\kappa/2} - \gamma + \mu + 1 + O_{L_0})) \)
- in Step 2(l)ii, since \( \beta \in L_1 \), it suffices to check if \( \beta + O_L \) is in \( \text{span}(a_{\kappa/2} - \gamma + 1, \ldots, a_{\kappa/2} - \gamma + \mu + 1) \) and \( \{0\} \)
- in Step 2k, we consider all elements \( \alpha \in L_\beta \), so \( f \) has domain \( \cup_{\beta \in L_1} L_\beta \times \{Z_{L_0}(\beta)\} \); but, \( f \) has domain \( \cup_{\beta \in L_1} (L_\beta - (L_0 + \beta + O_L) \times \{Z_{L_0}(\beta)\}) \) in [BSS08, proof of Proposition 6.9], because the values of \( f \) in \( \cup_{\beta \in L_1} (L_\beta + \beta + O_L) \times \{Z_{L_0}(\beta)\} \) are never queried; nonetheless, we choose to define \( f \) there as well, because doing so simplifies a lot of “index arithmetic” when implementing \( V_{\text{hs,=}^a} \) (and when decomposing \( V_{\text{hs,=}^a} \) into \( Q_{\text{hs,=}^a} \) and \( D_{\text{hs,=}^a} \)); cf. Footnote 24
B.2 PCP Verifier Specifications

Algorithm 8 $V_L$

inputs:
• $(x, 1^t)$, allegedly in the language $L$

randomness:
• $r_1 \cdots r_{\text{rand}_{\text{PCP}}(x,t)}$

oracle:
• $\pi$, probabilistically-checkable proof for the satisfiability of $(x, 1^t)$

1. $b \leftarrow V_{\text{sACSP}}^\pi((x, 1^t); r_1 \cdots r_{\text{rand}_{\text{PCP}}(x,t)})$
2. output $b$

notes:
• see Algorithm 1 for $P_L$, the corresponding verifier
• $V_{\text{sACSP}}$ has the choice of parameters $\text{Params}_L$ hardcoded
Algorithm 9 $V_{\text{SACP}}$

**inputs:**
- $(x,1^t)$, allegedly in $\text{sACP}$ with the given choice of parameters
  \[ (f, (m_n, t_n, H), (c_n, t_n, s_n, N), (t_p, s_p, P), (t_1, I)) \]

**randomness:**
- $r_1 \cdots r_{\text{rand}_{\text{SACP}}}(x,t)$

**oracle:**
- $\pi = (p_0, \pi_0, p_1, \pi_1, \pi_\epsilon)$, probabilistically-checkable proof for the claim “$(x,1^t) \in \text{sACP}$”

1. Parameter instantiation:
   (a) $I_t := \text{FindHRPoly}(1^f(t))$
   (b) $B_{F_t} := \text{FieldBasis}(I_t)$
   (c) $(B_H, \mathcal{O}_{H_t}) := \text{FindH}(1^t)$
   (d) for $i = 1, \ldots, c_n(t), \ [N_{t,i}]^\pi := \text{FindN}(1^t, i)$
   (e) $[P_t]^\alpha := \text{FindP}(1^t)$
   (f) $(B_{I_{\log |x|}}, \mathcal{O}_{I_{\log |x|}}) := \text{FindI}(1^t, 1^{\log |x|})$

2. Proximity of $p_0$ to $\text{RS}$:
   (a) $\delta_{RS} := (8 \sum_{i=1}^{c_n(t)} \deg(N_{t,i}))^{-1}$, $s'_{RS} := 0.5$, $R_{RS} := \text{rand}_{\text{RS}}(f(t), f(t), 2^{m_H(t)} - 1, \delta_{RS}, s'_{RS})$
   (b) $r_1' \cdots r_{r_{RS}}' := r_1 \cdots r_{R_{RS}}$
   (c) $b_{RS} := V_{\text{RS}}^{(p_0, \pi_0)}(I_t, B_{F_t}, 0_{F_t}, 2^{m_H(t)} - 1, \delta_{RS}, s'_{RS}; r_1' \cdots r_{R_{RS}}')$

3. Proximity of $p_1$ to $\text{VRS}$:
   (a) $d := \deg(P_t(x, x^{(2^{m_H(t)} - 1)} \deg(N_{t,i}), \ldots, x^{(2^{m_H(t)} - 1) \deg(N_{t,n}(\alpha))}))$
   (b) $\delta_{VRS} := s'_{VRS} := 0.5$, $R_{VRS} := \text{rand}_{\text{VRS}}(f(t), f(t), m_H(t), d, \delta_{VRS}, s'_{VRS})$
   (c) $r_1' \cdots r_{r_{VRS}}' := r_1 \cdots r_{R_{VRS}}$
   (d) $b_{VRS} := V_{\text{VRS}}^{(p_1, \pi_1)}(I_t, B_{F_t}, 0_{F_t}, B_{H_t}, \mathcal{O}_{H_t}, d, \delta_{VRS}, s'_{VRS}; r_1' \cdots r_{R_{VRS}}')$

4. Consistency of $p_0$ with the instance $(x,1^t)$:
   (a) $r_1^{(1)} \cdots r_{r(t)}^{(1)} := r_1 \cdots r_{f(t)}$
   (b) for $i = 1, \ldots, c_n(t), \alpha_i := [N_{t,i}]^\pi(\alpha)$
   (c) query $p_0$ at the following points: $\alpha_1, \ldots, \alpha_{c_n(t)}$
   (d) query $p_1$ at the point $\alpha$
   (e) $\omega := [P_t]^\alpha(\alpha, p_0(\alpha_1), \ldots, p_0(\alpha_{c_n(t)}))$
   (f) if $(\omega = p_1(\alpha))$, then $b_{\text{consist}} := 1$, else $b_{\text{consist}} := 0$

5. Consistency of $p_0$ with the instance $(x,1^t)$:
   (a) compute $A_x$, the low-degree extension of the function $f_x: I_{t,\log |x|} \rightarrow \{0,1\}$ defined by $f_x(\alpha_i) := x_i$ where $\alpha_i$ is the $i$-th element in $I_{t,\log |x|}$
   (b) $\delta_{\epsilon} := (8 \sum_{i=1}^{c_n(t)} \deg(N_{t,i}))^{-1}$, $s'_{\epsilon} := 0.5$, $R_{\epsilon} := \text{rand}_{\text{VRS}}(f(t), f(t), \log |x|, 2^{m_H(t)} - 1, \delta_{\epsilon}, s'_{\epsilon})$
   (c) $r_1' \cdots r_{r_{\epsilon}}' := r_1 \cdots r_{R_{\epsilon}}$
   (d) $b_{\text{inst}} := V_{\text{VRS}}^{(p_0, \pi_0)}(I_t, B_{F_t}, 0_{F_t}, B_{I_{\log |x|}}, \mathcal{O}_{I_{\log |x|}}, 2^{m_H(t)} - 1, \delta_{\epsilon}, s'_{\epsilon}; r_1' \cdots r_{R_{\epsilon}}')$, where $p_\epsilon$ is the evaluation of $A_x$ (note that $p_0 - p_{\epsilon}$ can be simulated with access to $p_0$ and $p_{\epsilon}$, and $p_{\epsilon}$ can be simulated by evaluating $A_x$)

6. $b := b_{RS} \land b_{VRS} \land b_{\text{consist}} \land b_{\text{inst}}$

7. output $b$

**notes:**
- reference: Construction 7.5
- see Lemma C.8 for complexity bounds on queries and randomness
- see Lemma 11.23 for the “non-adaptive decomposition” of $V_{\text{SACP}}$ into $Q_{\text{SACP}}$ and $D_{\text{SACP}}$
- see Algorithm 2 for $P_{\text{SACP}}$, the corresponding prover
- to amplify soundness beyond 1/2, there is of course no need to perform again Step 1, but one does need to re-draw fresh randomness for the other steps (proximity to RS, proximity to VRS, consistency check, and consistency with the instance)
Algorithm 10 $V_{aVRS}$

inputs:
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
- $B_S$ and $O_S$, basis and offset for the $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$
- $B_H$ and $O_H$, basis and offset for the $\lambda$-dimensional affine subspace $H \subseteq \mathbb{F}_{2^\ell}$
- $d$, positive integer indicating what “low-degree” means
- $\delta$, proximity parameter
- $s'$, target soundness
- $r_1 \cdots r_{\text{rand}_{aVRS}(\ell,\kappa,\lambda,d,\delta,s')}$

oracles:
- $p$, function from $S$ to $\mathbb{F}_{2^\ell}$
- $\pi = (\tilde{p}, \tilde{\pi})$, proof of proximity to $\text{VRS}(\mathbb{F}_{2^\ell}, S, H, d)$ for the function $p$

1. $m := \left\lceil \frac{\log(1 - s')}{\log(1 - \delta^{2\kappa})} \right\rceil$
2. for $i = 1, \ldots, m$:
   (a) $r_1^{(i)} \cdots r_{\text{rand}_{aVRS}(\ell,\kappa,\lambda,d)}^{(i)} := r_1^{(i-1)} \cdot \text{rand}_{aVRS}(\ell,\kappa,\lambda,d) + 1 \cdots r_{\text{rand}_{aVRS}(\ell,\kappa,\lambda,d)}^{(i)}$
   (b) $b_i := V_{aVRS}^{(p,\pi)}(I_\ell, B_S, O_S, B_H, O_H, d; r_1^{(i)} \cdots r_{\text{rand}_{aVRS}(\ell,\kappa,\lambda,d)}^{(i)})$
3. $b := b_1 \wedge \cdots \wedge b_m$
4. output $b$

notes:
- see Lemma C.7 for complexity bounds on queries and randomness
- see Lemma 11.22 for the “non-adaptive decomposition” of $V_{aVRS}$ into $Q_{aVRS}$ and $D_{aVRS}$
- see Algorithm 3 for $P_{aVRS}$, the corresponding prover (which is the same as that for $V_{aVRS}$)
- soundness amplification in Step 2a is done “directly”, without attention to randomness efficiency
- from Theorem 10.1, we know that $\left\lceil \frac{\log(1 - s')}{\log(1 - \delta^{2\kappa})} \right\rceil \leq \left\lceil \frac{1}{\text{VRS}(\delta,2^\kappa)} \right\rceil \leq \left\lceil \frac{1}{\delta} \left( 2 + \frac{2^{\alpha+1} \cdot \text{log}_2(\pi)}{1 - 2^{-\alpha}} \right) \right\rceil$
Algorithm 11 $V_{\text{aRS}}$

**inputs:**
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
- $B_S$ and $O_S$, basis and offset for the $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$
- $d$, positive integer indicating what “low-degree” means
- $\delta$, proximity parameter
- $s'$, target soundness

**randomness:**
- $r_1 \cdots r_{\text{rand}_{\text{aRS}}(\ell, \kappa, d, \delta, s')}$

**oracles:**
- $p$, function from $S$ to $\mathbb{F}_{2^\ell}$
- $\pi$, proof of proximity to $\text{RS}(\mathbb{F}_{2^\ell}, S, d)$ for the function $p$

1. $m := \lceil \frac{\log(1-s')}{\log(1-s_{\text{RS}}(\delta, 2^\kappa))} \rceil$
2. for $i = 1, \ldots, m$:
   (a) $r_1^{(i)} \cdots r_{\text{rand}_{\text{aRS}}(\ell, \kappa, d)}^{(i)} := r_1^{(i-1)} \text{rand}_{\text{aRS}}(\ell, \kappa, d) + \cdots + r_{\text{rand}_{\text{aRS}}(\ell, \kappa, d)}^{(i)}$
   (b) $b_i := V_{\text{aRS}}(p, \pi)(I_\ell, B_S, O_S, d; r_1^{(i)} \cdots r_{\text{rand}_{\text{aRS}}(\ell, \kappa, d)}^{(i)})$
3. $b := b_1 \land \cdots \land b_m$
4. output $b$

**notes:**
- see Lemma C.6 for complexity bounds on queries and randomness
- see Lemma 11.21 for the “non-adaptive decomposition” of $V_{\text{aRS}}$ into $Q_{\text{aRS}}$ and $D_{\text{aRS}}$
- see Algorithm 4 for $P_{\text{aRS}}$, the corresponding prover (which is the same as that for $V_{\text{aRS}}$)
- soundness amplification in Step 2a is done “directly”, without attention to randomness efficiency
- from Theorem 10.1, we know that $\left\lfloor \frac{\log(1-s')}{\log(1-s_{\text{RS}}(\delta, 2^\kappa))} \right\rfloor \leq \left\lfloor \frac{\frac{1}{s_{\text{RS}}(\delta, 2^\kappa)}}{\frac{1}{2}(1 + 2^{n+1+p\log\varepsilon}} \right\rfloor \leq \frac{1}{\frac{1}{2}(1 + 2^{n+1+p\log\varepsilon}} \right\rfloor$
Algorithm 12 $V_{\text{VRS}}$

inputs:
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
- $B_S$ and $O_S$, basis and offset for the $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$
- $B_H$ and $O_H$, basis and offset for the $\lambda$-dimensional affine subspace $H \subseteq \mathbb{F}_{2^\ell}$
- $d$, positive integer indicating what “low-degree” means

randomness:
- $r_1 \cdots r_{\text{randVRS}(\ell,\kappa,\lambda,d)}$

oracles:
- $p$, function from $S$ to $\mathbb{F}_{2^\ell}$
- $\pi = (\tilde{p}, \tilde{\pi})$, proof of proximity to $V_{\text{RS}}(\mathbb{F}_{2^\ell}, S, d - |H|)$

1. Proximity test of $\tilde{p}$ to $\text{RS}(\mathbb{F}_{2^\ell}, S, d - |H|)$:
   (a) $r_1' \cdots r_{\text{randRS}(\ell,\kappa,d-|H|)} := r_1' \cdots r_{\text{randRS}(\ell,\kappa,d-|H|)}$
   (b) $b_{\text{RS}} := V_{\text{RS}}^p(I_\ell, B_S, O_S, d - |H|; r_1' \cdots r_{\text{randRS}(\ell,\kappa,d-|H|)})$

2. Consistency check between $p$ and $\tilde{p}$:
   (a) $r_1^{(\alpha)} \cdots r_{\kappa}^{(\alpha)} := r_1 \cdots r_{\kappa}$
   (b) $\alpha := \text{GetRandElt}(I_\ell, B_S, O_S, (r_1^{(\alpha)}, \ldots, r_{\kappa}^{(\alpha)}))$
   (c) query $\alpha$ to $p$
   (d) query $\alpha$ to $\tilde{p}$
   (e) $[Z_H]^{\alpha} := \text{FindSubspPoly}(I_\ell, B_H, O_H)$
   (f) $\omega := [Z_H]^{\alpha}(\alpha)$
   (g) if $(p(\alpha) = \omega \cdot \tilde{p}(\alpha))$, then $b_{\text{consist}} := 1$, else $b_{\text{consist}} := 0$

3. $b := b_{\text{RS}} \land b_{\text{consist}}$
4. output $b$

notes:
- see Lemma C.5 for complexity bounds on queries and randomness
- see Lemma 11.20 for the “non-adaptive decomposition” of $V_{\text{VRS}}$ into $Q_{\text{VRS}}$ and $D_{\text{VRS}}$
- see Algorithm 3 for $P_{\text{VRS}}$, the corresponding prover
- it must be that $d \geq |H|$, otherwise $p$ is certainly not in $V_{\text{RS}}(\mathbb{F}_{2^\ell}, S, H, d)$
Algorithm 13 \( V_{RS} \)

inputs:
- \( I_\ell \), irreducible polynomial of degree \( \ell \) over \( \mathbb{F}_2 \) with root \( x \), inducing the field extension \( \mathbb{F}_{2^\ell} := \mathbb{F}_2(x) \)
- \( B_S \) and \( O_S \), basis and offset for the \( \kappa \)-dimensional affine subspace \( S \subseteq \mathbb{F}_{2^\ell} \)
- \( d \), positive integer indicating what “low-degree” means

randomness:
- \( r_1 \cdots r_{\text{rand}_{RS}(\ell, \kappa, d)} \)

oracles:
- \( p \), function from \( S \) to \( \mathbb{F}_{2^\ell} \)
- \( \pi \), proof of proximity to \( \text{RS}(\mathbb{F}_{2^\ell}, S, d) \) for the function \( p \)

1. if \( \kappa \leq \eta \), then:
   a. for \( i = 1, \ldots, 2^\kappa \):
      i. \( \alpha_i := \text{GetEltWithIndex}(I_\ell, B_S, O_S, i) \)
      ii. query \( \alpha_i \) to \( p \)
   b. \( P := \text{SubspaceInterp}(I_\ell, B_S, O_S, (p(\alpha_1), \ldots, p(\alpha_{2^\kappa}))) \)
   c. \( \bar{d} := \deg(P) \)
   d. if \( \bar{d} \leq d \), output 1, else output 0

2. if \( \kappa > \eta \), then:
   a. \( d_{\kappa, \eta} := |S|/2^\eta - 1 = 2^\kappa/2^\eta - 1 \)
   b. if \( d < d_{\kappa, \eta} \), then output \( b := V_{RS,(\leq)}^{(p, \pi)}(I_\ell, B_S, O_S, d; r_1 \cdots r_{\text{rand}_{RS,(\leq)}(\ell, \kappa, d)}) \)
   c. if \( d = d_{\kappa, \eta} \), then output \( b := V_{RS,(=)}^{(p, \pi)}(I_\ell, B_S, O_S; r_1 \cdots r_{\text{rand}_{RS,(=)}(\ell, \kappa)}) \)
   d. if \( d > d_{\kappa, \eta} \), then output \( b := V_{RS,(>)}^{(p, \pi)}(I_\ell, B_S, O_S, d; r_1 \cdots r_{\text{rand}_{RS,(>)}(\ell, \kappa, d)}) \)

notes:
- see Lemma C.4 for complexity bounds on queries and randomness
- see Lemma 11.19 for the “non-adaptive decomposition” of \( V_{RS} \) into \( Q_{RS} \) and \( D_{RS} \)
- see Algorithm 4 for \( P_{RS} \), the corresponding prover
- if \( \kappa \leq \eta \), then \( V_{RS} \) can just check directly whether \( p \) is in \( \text{RS}(\mathbb{F}_{2^\ell}, S, d) \) or not

115
Algorithm 14 $V_{RS,\eta}$

**inputs:**
- $I_\ell$, irreducible polynomial of degree $\ell$ over $F_2$ with root $x$, inducing the field extension $F_{2^\ell} := F_2(x)$
- $B_S$ and $O_S$, basis and offset for the $\kappa$-dimensional affine subset $S \subseteq F_{2^\ell}$
- $d$, positive integer, greater than $|S|/2^n - 1$, indicating what “low-degree” means

**randomness:**
- $r_1 \cdots r_{\text{rand}_{RS,\eta}(\ell,\kappa,d)}$

**oracles:**
- $p$, function from $S$ to $F_{2^n}$
- $\pi = ((p_0, \tau_0), \ldots, (p_{2^n-1}, \tau_{2^n-1}))$, proof of proximity to $RS(F_{2^n}, S, d)$ for the function $p$

1. if $d \geq |S|$, then output $b := 1$
2. if $d < |S|$, then:
   a. $d_{\kappa,\eta} := |S|/2^n - 1 = 2^\kappa/2^n - 1$
   b. $m_{\kappa,\eta,d} := [(d + 1)/(d_{\kappa,\eta} + 1)]$
   c. $r_1^{(\tau)} \cdots r_{\kappa}^{(\tau)} := r_1 \cdots r_{\kappa}$
   d. $\tau := \text{GetRandElit}(I_\ell, B_S, O_S, (r_1^{(\tau)}, \ldots, r_{\kappa}^{(\tau)}))$
   e. query $\tau$ to $p$
   f. for $i = 0, \ldots, m_{\kappa,\eta,d} - 1$:
      i. $r_1^{(i)} \cdots r_{\kappa}^{(i)} := r_1 \cdots r_{\text{rand}_{RS,\eta}(\ell,\kappa)}$
      ii. query $\tau$ to $p_i$
      iii. $b_i := V_{RS,\eta}(I_\ell, B_S, O_S, d_{\kappa,\eta}^{i+1}, r_1^{(i)} \cdots r_{\kappa}^{(i)})$
   g. if $m_{\kappa,\eta,d} \cdot (d_{\kappa,\eta} + 1) = d + 1$, then:
      i. $\omega_\tau := \sum_{i=0}^{m_{\kappa,\eta,d} - 1} p_i(\tau)$
      ii. if $p(\tau) = \omega_\tau$, then $b_{\text{consist}} := 1$, else $b_{\text{consist}} := 0$
      iii. $b := b_0 \land \cdots \land b_{m_{\kappa,\eta,d} - 1} \land b_{\text{consist}}$
      iv. output $b$
   h. if $m_{\kappa,\eta,d} \cdot (d_{\kappa,\eta} + 1) < d + 1$, then:
      i. $d_{\kappa,\eta,d} := d - m_{\kappa,\eta,d} \cdot (d_{\kappa,\eta} + 1)$
      ii. $r_1^{(m_{\kappa,\eta,d})} \cdots r_{\kappa}^{(m_{\kappa,\eta,d})} := r_1 \cdots r_{\text{rand}_{RS,\eta}(\ell,\kappa,d_{\kappa,\eta},d)}$
      iii. $b_{m_{\kappa,\eta,d}} := V_{RS,\eta}(I_\ell, B_S, O_S, d_{\kappa,\eta}^{d_{\kappa,\eta} + 1}, r_1^{(m_{\kappa,\eta,d})} \cdots r_{\kappa}^{(m_{\kappa,\eta,d})})$
      iv. query $\tau$ to $p_{m_{\kappa,\eta,d}}$
      v. $\omega_\tau := \sum_{i=0}^{m_{\kappa,\eta,d} - 1} p_i(\tau)$
      vi. if $p(\tau) = \omega_\tau$, then $b_{\text{consist}} := 1$, else $b_{\text{consist}} := 0$
      vii. $b := b_0 \land \cdots \land b_{m_{\kappa,\eta,d} - 1} \land b_{m_{\kappa,\eta,d}} \land b_{\text{consist}}$
      viii. output $b$

**notes:**
- see Lemma C.3 for complexity bounds on queries and randomness
- see Lemma 11.18 for the “non-adaptive decomposition” of $V_{RS,\eta}$ into $Q_{RS,\eta}$ and $D_{RS,\eta}$
- see Algorithm 5 for $P_{RS,\eta}$, the corresponding prover
- if $d \geq |S|$, every function $p : S \to F_{2^n}$ is in $RS(F_{2^n}, S, d)$ (cf. Step 1)
- if $d < |S|$, then $[(d + 1)/(d_{\kappa,\eta} + 1)] \in \{0, \ldots, 2^n\}$, because $|S| = 2^n \cdot (d_{\kappa,\eta} + 1)$

116
Algorithm 15 $V_{\text{RS},<}$

**inputs:**
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
- $B_S$ and $O_S$, basis for the $\kappa$-dimensional affine subset $S \subseteq \mathbb{F}_{2^\ell}$
- $d$, positive integer, less than $|S|/2^\eta - 1$, indicating what “low-degree” means

**randomness:**
- $\cdot r_1 \cdots r_{\text{rand}_{\text{RS},<}(\ell,\kappa,d)}$

**oracles:**
- $p$, function from $S$ to $\mathbb{F}_{2^\ell}$
- $\pi = (\pi_1, \pi_2)$, proof of proximity to $\text{RS}(\mathbb{F}_{2^\ell}, S, d)$ for the function $p$

1. $d_{\kappa,\eta} := |S|/2^n - 1 = 2^\kappa/2^n - 1$
2. $r'_1 \cdots r'_{\text{rand}_{\text{RS},<}(\ell,\kappa)} := r_1 \cdots r_{\text{rand}_{\text{RS},<}(\ell,\kappa)}$
3. $b_1 := V_{\text{RS},<}^{(p,\pi_1)}(I_\ell, B_S, O_S; r'_1 \cdots r'_{\text{rand}_{\text{RS},<}(\ell,\kappa)})$
4. $r''_1 \cdots r''_{\text{rand}_{\text{RS},<}(\ell,\kappa)} := r_1 \cdots r_{\text{rand}_{\text{RS},<}(\ell,\kappa)}$
5. Compute the polynomial $Q(x) := x^{d_{\kappa,\eta} - d} \in \mathbb{F}_{2^\ell}[x]$
6. “$p' := p \cdot Q$” (see notes below)
7. $b_2 := V_{\text{RS},<}^{(p',\pi_2)}(I_\ell, B_S, O_S; r''_1 \cdots r''_{\text{rand}_{\text{RS},<}(\ell,\kappa)})$
8. $b := b_1 \land b_2$
9. Output $b$

**notes:**
- see Lemma C.2 for complexity bounds on queries and randomness
- see Lemma 11.17 for the “non-adaptive decomposition” of $V_{\text{RS},<}$ into $Q_{\text{RS},<}$ and $D_{\text{RS},<}$
- see Algorithm 6 for $P_{\text{RS},<}$, the corresponding prover
- in Step 7, we must simulate the implicit input $p'$ (which is also a function from $S$ to $\mathbb{F}_{2^\ell}$), and we do so as follows: for each query $\alpha$, query $\alpha$ to the (real) implicit input $p$ and then return $p(\alpha) \cdot Q(\alpha)$; note that $Q(\alpha)$ can be evaluated in time that is $\text{poly}(\ell, \log(d_{\kappa,\eta} - d))$
Algorithm 16 $V_{\text{RS}.,}$

**inputs:**
- $I_{\ell}$, irreducible polynomial of degree $\ell$ over $F_2$ with root $\alpha$, inducing the field extension $F_2\ell := F_2(\alpha)$
- $B_L = (a_1, \ldots, a_\kappa)$ and $O_L$, basis and offset for the $\kappa$-dimensional affine subset $L \subseteq F_2^\ell$

**randomness:**
- $r_1 \cdots r_{\text{rand}_{\text{RS},.}(\ell, \kappa)}$

**oracles:**
- $p$, function from $L$ to $F_2^\ell$
- $\pi = (f, \Pi)$, proof of proximity to $\text{RS}(F_2^\ell, L, |L|/2^n - 1)$ for the function $p$

1. if $\kappa \leq \kappa_0$, then:
   (a) for $i = 1, \ldots, 2^\kappa$:
      i. $\alpha_i := \text{GetEltWithIndex}(I_{\ell}, B_L, O_L, i)$
      ii. query $\alpha_i$ to $p$
   (b) $d_{\kappa, \eta} := |L|/2^n - 1 = 2^\kappa/2^n - 1$
   (c) $P := \text{SubspaceInterp}(I_{\ell}, B_L, O_L, (p(\alpha_1), \ldots, p(\alpha_{2^\kappa})))$
   (d) $d := \deg(P)$
   (e) if $d \leq d_{\kappa, \eta}$, output 1, else output 0

2. if $\kappa > \kappa_0$, then:
   (a) $B_{L_0} := (a_1, \ldots, a_{\lceil \kappa/2 \rceil - \gamma}, O_{L_0} := O_L$
   (b) $[Z_{L_0}]^\kappa := \text{FindSubspoly}(I_{\ell}, B_{L_0}, O_{L_0})$
   (c) $B_{L_0}^\beta := (a_1, \ldots, a_{\lceil \kappa/2 \rceil - \gamma + \mu}, O_{L_0}^\beta := O_L$
   (d) if $r_1 = 0$, then do a random row test:
      i. $m := 1 + \lceil \kappa/2 \rceil$
      ii. $B_{L_1} := (a_{\lceil \kappa/2 \rceil - \gamma + 1}, \ldots, a_{\kappa}) O_{L_1} := O_L$
      iii. $\beta := \text{GetRanDelt}(I_{\ell}, B_{L_0}, O_{L_0}, (r_2, \ldots, r_{1+\lceil \kappa/2 \rceil + \gamma})$
      iv. if $\beta \in L_0^\beta$, then $B_{L_0} := (a_1, \ldots, a_{\lceil \kappa/2 \rceil - \gamma + \mu}, a_{\lceil \kappa/2 \rceil - \gamma + \mu + 1};$
      v. if $\beta \notin L_0^\beta$, then $B_{L_0} := (a_1, \ldots, a_{\lceil \kappa/2 \rceil - \gamma + \mu}, \beta + O_{L_0}^\beta)$
   vi. $O_{L_0} := O_{L_0}^\beta$
   vii. $\beta' := [Z_{L_0}]^\kappa(\beta)$
   viii. $b := V_{\eta, \kappa_0, \gamma, \mu}^1(I_{\ell}, B_{L_0}, O_{L_0} ; r_{m+1} \cdots r_{\text{rand}_{\text{RS},.}(\ell, \kappa)})$
   ix. output $b$
   (e) if $r_1 = 1$, then do a random column test:
      i. $m := 1 + \lceil \kappa/2 \rceil - \gamma + \mu$
      ii. $\alpha := \text{GetRandElt}(I_{\ell}, B_{L_0}, O_{L_0}, (r_2, \ldots, r_{1+\lceil \kappa/2 \rceil - \gamma + \mu})$
      iii. $B_{Z_{L_0}(L_1)} := ([Z_{L_0}]^\kappa(a_{\lceil \kappa/2 \rceil - \gamma + 1}) + [Z_{L_0}]^\kappa(0_{F_2^\ell}), \ldots, [Z_{L_0}]^\kappa(a_{\kappa}) + [Z_{L_0}]^\kappa(0_{F_2^\ell}))$
      iv. $O_{Z_{L_0}(L_1)} := [Z_{L_0}]^\kappa(O_{L_0})$
      v. $b := V_{\eta, \kappa_0, \gamma, \mu}^1(I_{\ell}, B_{Z_{L_0}(L_1)}, O_{Z_{L_0}(L_1)} ; r_{m+1} \cdots r_{\text{rand}_{\text{RS},.}(\ell, \kappa)})$
   x. output $b$

**notes:**
- see Theorem 10.3 for how the parameters $(\eta, \kappa_0, \gamma, \mu)$ can be chosen
- see Lemma C.1 for complexity bounds on queries and randomness
- see Lemma 11.16 for the “non-adaptive decomposition” of $V_{\eta, \kappa, \gamma}$ and $D_{\eta, \kappa}$
- see Algorithm 7 for $P_{\eta, \kappa}$, the corresponding prover
- in Step 2(d)ii, $\tilde{f}_{L_0}^{\alpha, \beta'}$ is a function with domain $L_{\beta} \times \beta'$ that is simulated as follows: for each query $\alpha \in L_{\beta}$ to $\tilde{f}_{L_0}^{\alpha, \beta'}$, if $Z_{L_0}(\alpha) = \beta'$ then return $p(\alpha)$, else return $f(\alpha, \beta')$
- in Step 2(e)iv, $\tilde{f}_{L_0}^{\alpha}$ is a function with domain $\{ \alpha \} \times Z_{L_0}(L_1)$ that is simulated as follows: for each query $\beta' \in Z_{L_0}(L_1)$ to $\tilde{f}_{L_0}^{\alpha}$, if $Z_{L_0}(\alpha) = \beta'$ then return $p(\alpha)$, else return $f(\alpha, \beta')$

118
B.3 Finite Field Algorithms

In this section we provide the finite-field algorithms that we used in the pseudocode listings in Section B.1 and Section B.2 (and also those in Section 11). These algorithms provide certain basic computations in extension fields of \( \mathbb{F}_2 \), and almost all are adapted to the important special case of affine subspaces. Throughout, we let \( S \) denote a \( \kappa \)-dimensional affine subspace of the appropriate extension field of \( \mathbb{F}_2 \), specified via a basis \( B_S \) and an offset \( O_S \).

We begin with a summary of the algorithms described in this section, and following are the pseudocode listings.

- **Set up:**
  - \( \text{FindIrrPoly}(1^\ell) \) outputs an irreducible polynomial \( I_\ell \) of degree \( \ell \) over \( \mathbb{F}_2 \) with a root \( x \)
  - \( \text{FieldBasis}(I_\ell) \) outputs a (canonical) basis \( B_\mathbb{F} \) for the field \( \mathbb{F} := \mathbb{F}_2(x) \)

- **Selecting field elements of affine subspaces:**
  - \( \text{GetRandElt}(I_\ell, B_S, O_S, (r_1, \ldots, r_\kappa)) \) outputs a field element in the affine subspace \( S \) according to the random binary string \( (r_1, \ldots, r_\kappa) \)
  - \( \text{GetEltWithIndex}(I_\ell, B_S, O_S, i) \) outputs the \( i \)-th field element in the affine subspace \( S \) according to a canonical order

- **Multi-point evaluation and interpolation over affine subspaces:**
  - \( \text{SubspaceEval}(I_\ell, B_S, O_S, P) \) outputs the evaluation of \( P(x) \) over the affine subspace \( S \)
  - \( \text{SubspaceInterp}(I_\ell, B_S, O_S, (\alpha_0, \ldots, \alpha_{2^\kappa - 1})) \) outputs the interpolation of \( (\alpha_0, \ldots, \alpha_{2^\kappa - 1}) \) over the affine subspace \( S \)

- **Some operations involving vanishing polynomials for affine subspaces:**
  - \( \text{FindSubspPoly}(I_\ell, B_S, O_S) \) outputs an arithmetic circuit \( [Z_S]^A \) for computing the vanishing polynomial \( Z_S(x) \) of the affine subspace \( S \)
  - \( \text{FindBivariate}(I_\ell, B_S, O_S, P) \) outputs \( Q(x, y) := P(x) \mod (y - Z_S(x)) \)
  - \( \text{SubspaceDivide}(I_\ell, B_S, O_S, P) \) outputs \( \tilde{P}(x) := P(x)/Z_S(x) \), if \( P(x) \equiv 0 \mod Z_S(x) \)
Algorithm 17 FindIrrPoly

**inputs:**
- $1^\ell$, desired degree presented in unary

**output:**
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$

1. the algorithm of [Sho88, Corollary 3.2], which runs in time $\text{poly}(\ell)$

**notes:**
- the algorithm for finding irreducible polynomials is the only one that we do not spell out explicitly, because we do not plan to use it in practice; indeed, in practice, pre-computed tables of irreducible polynomials work much better

Algorithm 18 FieldBasis

**inputs:**
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$

**output:**
- $B_{\mathbb{F}_{2^\ell}}$, basis for $\mathbb{F}_{2^\ell}$ when viewed as an $\ell$-dimensional vector space over $\mathbb{F}_2$

1. output $1, x, \ldots, x^{\ell-1}$

**notes:**
- an optimization that is left to future work is the use of normal bases [Gao93]
**Algorithm 19 GetRandElt**

**inputs:**
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
- $B_S = (a_1, \ldots, a_\kappa)$ and $O_S$, basis and offset for the $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$
- $(r_1, \ldots, r_\kappa)$, random binary string used to select the element of $S$

**output:**
- $\alpha$, selected element of $S$

1. $\alpha := \left(\sum_{j=1}^\kappa r_j a_j\right) + O_S$
2. output $\alpha$

**notes:**
- the random bits are simply the coefficients of the linear combination

---

**Algorithm 20 GetEltWithIndex**

**inputs:**
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
- $B_S = (a_1, \ldots, a_\kappa)$ and $O_S$, basis and offset for the $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$
- $i$, index in $\{1, \ldots, 2^\kappa\}$ of the desired element of $S$

**output:**
- $\alpha$, selected element of $S$

1. $\alpha := \left(\sum_{j=1}^\kappa i_j a_j\right) + O_S$
2. output $\alpha$

**notes:**
- $i_1 \cdots i_\kappa$ is $(i-1)$ in binary
Algorithm 21 FINDSUBSPPOLY

inputs:
- $I_{\ell}$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
- $\mathcal{B}_S = (a_1, \ldots, a_\kappa)$ and $\mathcal{O}_S$, basis and offset for the $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$

output:
- $[Z_S]^\kappa$, an $O(\kappa)$ arithmetic circuit for computing $Z_S(x) = \sum_{i=0}^\kappa \beta_i x^{2i} + \gamma$, the vanishing polynomial for the affine subspace $S$

1. let $[Z_{S_1}]^\kappa$ be the arithmetic circuit for $Z_{S_1}(x) := x \cdot (x + a_1)$
2. if $\kappa = 1$, then:
   (a) use $[Z_{S_1}]^\kappa$ to compute the arithmetic circuit $[Z_S]^\kappa$ for $Z_S(x) := Z_{S_1}(x) + Z_{S_1}(\mathcal{O}_S)$
   (b) output $[Z_S]^\kappa$
3. if $\kappa > 1$, then:
   (a) for $j = 2, \ldots, \kappa$:
      i. use $[Z_{S_{j-1}}]^\kappa$ to compute $\alpha_j := Z_{S_{j-1}}(a_j)$
      ii. use $[Z_{S_{j-1}}]^\kappa$ to compute the arithmetic circuit $[Z_{S_j}]^\kappa$ for $Z_{S_j}(x) := Z_{S_{j-1}}(x^2) + \alpha_1 Z_{S_{j-1}}(x)$
   (b) use $[Z_{S_{\kappa-1}}]^\kappa$ to compute the arithmetic circuit $[Z_S]^\kappa$ for $Z_S(x) := Z_{S_{\kappa-1}}(x) + Z_{S_{\kappa-1}}(\mathcal{O}_S)$
   (c) output $[Z_S]^\kappa$

notes:
- the algorithm uses the simple recursion

\[
Z_{\text{span}(a_1, \ldots, a_\kappa)}(x) = Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(x)Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(x + a_\kappa) \\
= Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(x) \cdot (Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(x) + Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(a_\kappa)) \\
= Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(x^2) + Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(a_\kappa) \cdot Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(x) \\
= Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(x^2) + Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(a_\kappa) \cdot Z_{\text{span}(a_1, \ldots, a_{\kappa-1})}(x)
\]

together with the fact that

\[
Z_{\text{span}(a_1, \ldots, a_\kappa)}(x + \mathcal{O}) = Z_{\text{span}(a_1, \ldots, a_\kappa)}(x + \mathcal{O}) = Z_{\text{span}(a_1, \ldots, a_\kappa)}(x) + Z_{\text{span}(a_1, \ldots, a_\kappa)}(\mathcal{O})
\]
Algorithm 22 SubspaceEval

inputs:
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
- $B_S = (a_1, \ldots, a_\kappa)$ and $O_S$, basis and offset for the $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$
- $P(x) = \sum_{i=0}^{d} \beta_i x^i$, polynomial over $\mathbb{F}_{2^\ell}[x]$ with $d < 2^\kappa$

output:
- $(\alpha_0, \ldots, \alpha_{2^\kappa-1})$, elements in $\mathbb{F}_{2^\ell}$ such that $P(\sum_{i=1}^{\kappa} b_i a_i) = \alpha_0 \sum_{i=1}^{\kappa} b_i 2^i - 1$ for $b_1 \cdots b_\kappa \in \{0, 1\}^\kappa$

1. output $(\alpha_0, \ldots, \alpha_{2^\kappa-1}) := A(I_\ell, B_S, O_S, P, 0)$, where $A$ is defined below

Define $A(I_\ell, (a_1, \ldots, a_\kappa), O, P, j)$ as follows:
1. if $\kappa = 1$, return $P(a_j 2^\kappa)$ and $P(a_j 2^\kappa+1)$
2. if $\kappa > 1$:
   a. use FINDSUBSPOLY to find (an arithmetic circuit for) $Z_{\text{span}(a_1, \ldots, a_{\kappa-1})+O}(x)$.
   b. compute $\beta := Z_{\text{span}(a_1, \ldots, a_{\kappa-1})+O}(a_j 2^\kappa)$
   c. divide $P(x)$ by $Z_{\text{span}(a_1, \ldots, a_{\kappa-1})+O}(x) - \beta$ to obtain a quotient $Q(x)$ and remainder $R(x)$
   d. compute $P_0(x) := R(x)$
   e. compute $P_1(x) := R(x) + Z_{\text{span}(a_1, \ldots, a_{\kappa-1})+O}(a_\kappa) \cdot Q(x)$
   f. compute $(a_j 2^\kappa, \ldots, a_j 2^\kappa+2^{\kappa-1}) := A(I_\ell, (a_1, \ldots, a_{\kappa-1}), O, P_0, j)$
   g. compute $(a_j 2^\kappa+2^{\kappa-1}, \ldots, a_j 2^{\kappa+1}) := A(I_\ell, (a_1, \ldots, a_{\kappa-1}), O, P_1, j+2^{\kappa-1})$
   h. output $(a_j 2^\kappa, \ldots, a_j 2^{\kappa+1})$

notes:
- see [Mat08, Figure 3.1] for a discussion (of the linear subspace case) and more references
- in an implementation, the vanishing polynomials would be pre-computed first
Algorithm 23 \textsc{SubspaceInterp}

\textbf{inputs:}
\begin{itemize}
  \item $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
  \item $B_S = (a_1, \ldots, a_\kappa)$ and $O_S$, basis and offset for the $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$
  \item $(\alpha_0, \ldots, \alpha_{2^\ell-1})$, elements in $\mathbb{F}_{2^\ell}$
\end{itemize}

\textbf{output:}
\begin{itemize}
  \item $P(x) = \sum_{i=0}^d \beta_i x^i$, with $d < 2^\kappa$, such that $P(\sum_{i=1}^{2^\kappa-1} b_i a_i) = \alpha \sum_{i=1}^{2^\kappa-1} b_i 2^{2^\kappa-1}$ for $b_1 \cdots b_\kappa \in \{0, 1\}^\kappa$
\end{itemize}

1. output $P := A(I_\ell, B_S, O_S, (\alpha_0, \ldots, \alpha_{2^\ell-1}), 0)$, where $A$ is defined below

Define $A(I_\ell, (a_1, \ldots, a_\kappa), O, (\alpha_0, \ldots, \alpha_{2^\ell-1}), j)$ as follows:

1. if $\kappa = 1$, return $(x - \alpha_{2^\ell}) \cdot (x - \alpha_{2^\ell+1})$
2. if $\kappa > 1$:
   \begin{itemize}
     \item (a) compute $P_0(x) := A(I_\ell, (a_1, \ldots, a_{\kappa-1}), O, (\alpha_{2^\ell}, \ldots, \alpha_{2^\ell+2^\ell-1-1}), j)$
     \item (b) compute $P_1(x) := A(I_\ell, (a_1, \ldots, a_{\kappa-1}), O, (\alpha_{2^\ell+2^\ell-1}, \ldots, \alpha_{(j+1)2^\ell-1}), j + 2^\ell-1)$
     \item (c) use \textsc{FindSubspPoly} to find $\text{Span}(a_1, \ldots, a_{\kappa-1}) + O(x)$
     \item (d) compute $\beta := \text{Span}(a_1, \ldots, a_{\kappa-1}) + O(a_{2^\ell})$
     \item (e) compute $R(x) := P_0(x)$
     \item (f) compute $Q(x) := (P_1(x) - P_0(x))/\beta$
     \item (g) compute $P(x) := Q(x) \cdot (\text{Span}(a_1, \ldots, a_{\kappa-1}) + O(x) - \beta) + R(x)$
     \item (h) output $P(x)$
   \end{itemize}

\textbf{notes:}
\begin{itemize}
  \item this is simply the “dual” of Algorithm 22
Algorithm 24 

**SubspaceDivide**

**inputs:**
- \( I_t \), irreducible polynomial of degree \( t \) over \( \mathbb{F}_2 \) with root \( x \), inducing the field extension \( \mathbb{F}_{2^t} := \mathbb{F}_2(x) \)
- \( B_S = (a_1, \ldots, a_n) \) and \( O_S \), basis for the \( \kappa \)-dimensional affine subspace \( S \subseteq \mathbb{F}_{2^t} \)
- \( P(x) = \sum_{i=0}^d \beta_i x^i \), polynomial over \( \mathbb{F}_{2^t}[x] \) with \( d < 2^t \) such that \( P(x) \equiv 0 \mod Z_S(x) \)

**output:**
- \( \tilde{P}(x) \), polynomial equal to \( P(x)/Z_S(x) \)

1. \( \tilde{P}(x) := 0 \)
2. if \( \deg(P) < 2^\kappa \), output \( \tilde{P}(x) := 0 \); otherwise continue
3. \( Z_S(x) = \sum_{i=0}^{\kappa} \beta_i x^i + \omega_0 := \text{FindSubSpPoly}(I_t, B_S, O_S) \)
4. let \( t \) be such that \( 2^t \leq \deg(P) < 2^{t+1} \); note that \( \kappa \leq t \)
5. \( R_0(x) := Z_S(x) - x^{2^\kappa} = \sum_{i=0}^{\kappa} \beta_i x^i + \omega_0 \)
6. for \( j = 1, \ldots, t-k \) compute \( R_j(x) := R_{j-1}(x)^2 = R_{j-1}(x^2) \)
7. \( P_0(x) := P(x) \)
8. for \( j = 1, \ldots, t-\kappa+1 \):
   - (a) by induction, \( \deg(P_{j-1}) < 2^{t-(j-1)+1} \)
   - (b) if \( \deg(P_{j-1}) < 2^{t-(j-1)} \), set \( P_j(x) := P_{j-1}(x) \) and go to next iteration of the loop
   - (c) if \( \deg(P_{j-1}) \geq 2^{t-(j-1)} \), continue this iteration
   - (d) write \( P_{j-1}(x) = x^{2^{t-j+1}} P_{j-1}^{(1)}(x) + P_{j-1}^{(0)}(x) \) with \( \deg(P_{j-1}) \leq \deg(P_{j-1}) - 2^{t-j+1} \) and \( \deg(P_{j-0}) < 2^{t-j+1} \) and note that
     \[
     P_{j-1}(x) = (x^{2^{t-j+1}} + R_{t-\kappa+1-j}(x)) P_{j-1}^{(1)}(x) + P_{j-1}^{(0)}(x) = Z_S(x)^{2^{t-\kappa+1-j}} P_{j-1}^{(1)}(x) + P_{j-1}^{(0)}(x)
     \]
     where \( P_{j-1}^{(1)}(x) := R_{t-\kappa+1-j}(x) \cdot P_{j-1}^{(1)}(x) + P_{j-1}^{(0)}(x) \)
   - (e) set \( \tilde{P}(x) := \tilde{P}(x) + Z_S(x)^{2^{t-\kappa+1-j}} P_{j-1}^{(1)}(x) \)
   - (f) write \( P_{j-1}^{(1)}(x) = x^{2^{t-j+1}} P_{j-1}^{(1)}(x) + P_{j-1}^{(0)}(x) \) with \( \deg_x(P_{j-1}^{(1)}) \leq \deg_x(P_{j-1}) - 2^{t-j+1} + 2^{t-\kappa+1-j} \) and \( \deg_x(P_{j-0}^{(1)}) < 2^{t-j+1} \) and note that
     \[
     P_{j-1}^{(1)}(x) = (x^{2^{t-j+1}} + R_{t-\kappa+1-j}(x)) P_{j-1}^{(1)}(x) + P_{j}^{(1)}(x) + P_{j-1}^{(1)}(x) + P_{j-1}^{(0)}(x) \)
     where \( P_{j}^{(1)}(x) := R_{t-\kappa+1-j}(x) \cdot P_{j-1}^{(1)}(x) + P_{j-1}^{(0)}(x) + P_{j-1}^{(0)}(x) \) and note that \( \deg(P_{j}) < 2^{t-j+1} \)
   - (g) set \( \tilde{P}(x) := \tilde{P}(x) + Z_S(x)^{2^{t-\kappa+1-j}} P_{j-1}^{(1)}(x) \)
9. output \( \tilde{P}(x) \)

**notes:**
- Step 5 and Step 6 construct a \((t - \kappa + 1)\)-line table, and in each line of the table there is a large power of 2 of \( Z_S(x) - x^{2^\kappa} \)
- in each iteration of the loop in Step 8 we divide out a large power of \( Z_S(x) \) twice, and these two divisions will jointly halve the degree of the remaining polynomial, and that is why we only need few iterations (i.e., \( t - \kappa + 1 \) iterations)
- in order to compute \( Z_S(x)^{2^{t-\kappa+1-j-1}} P_{j-1}^{(1)}(x) \) and \( Z_S(x)^{2^{t-\kappa+1-j-1}} P_{j-1}^{(1)}(x) \), respectively in Step 8e and in Step 8g, we should remember that
  \[
  Z_S(x)^{2^{t-\kappa+1-j-1}} = \prod_{i=0}^{t-\kappa-j} Z_S(x)^2 = \prod_{i=0}^{t-\kappa-j} (x^{2^i} + R_{t-\kappa-j}(x)), \text{ so that we should evaluate the product “from right to left” (i.e., multiply each of the terms of the product with } P_{j-1}^{(1)}(x) \text{ or } P_{j-1}^{(1)}(x), \text{ instead of first evaluating the big product and then multiplying the result with } P_{j-1}^{(1)}(x) \text{ or } P_{j-1}^{(1)}(x) \text{)}
  \]
Algorithm 25 FindBivariate

inputs:
- $I_\ell$, irreducible polynomial of degree $\ell$ over $\mathbb{F}_2$ with root $x$, inducing the field extension $\mathbb{F}_{2^\ell} := \mathbb{F}_2(x)$
- $\mathcal{B}_S = \{a_1, \ldots, a_n\}$ and $\mathcal{O}_S$, basis for the $\kappa$-dimensional affine subspace $S \subseteq \mathbb{F}_{2^\ell}$
- $P(x) = \sum_{i=0}^d \beta_i x^i$, polynomial over $\mathbb{F}_{2^t}[x]$

output:
- $Q(x, y)$, bivariate polynomial equal to $P(x) \mod (y - Z_S(x))$; note that $\deg_x(Q) < 2^\kappa$ and $\deg_y(Q) = \lceil \frac{\deg(P)}{2^{2^\ell}} \rceil$

1. if $\deg(P) < 2^\kappa$, output $Q(x, y) := P(x)$; otherwise continue
2. $Z_S(x) = \sum_{i=0}^\kappa \beta_i x^i + \omega_0 := \text{FindSubspPoly}(I_\ell, \mathcal{B}_S, \mathcal{O}_S)$
3. let $t$ be such that $2^{t+1} \leq \deg(P) < 2^{t+2}$; note that $\kappa \leq t$
4. $R_0(x, y) := y + (Z_S(x) - x^{2^\kappa}) = y + \sum_{i=0}^{\kappa-1} \beta_i x^{2^i} + \omega_0$
5. For $j = 1, \ldots, t - \kappa$:
   - $R_j(x, y) := \sum_{i=1}^j a_{t-i} y^{2^i} + \sum_{i=1}^{\kappa-1} (\gamma_{\kappa-1} - \gamma_i) x^{2^i} + \gamma_{\kappa-1} \beta_{t-i} x + \omega_{j-1} + \gamma_{\kappa-1} \omega_0$
   - where $R_{j-1}(x, y) = \sum_{i=0}^{\kappa-1} a_i y^{2^i} + \sum_{i=0}^{\kappa-1} \gamma_i x^{2^i} + \omega_{j-1}$
6. $P_0(x, y) := P(x)$
7. For $j = 1, \ldots, t - \kappa + 1$:
   - (a) by induction, $\deg_x(P_{j-1}) < 2^{t-(j-1)+1}$
   - (b) if $\deg_x(P_{j-1}) < 2^{t-(j-1)}$, set $P_j(x, y) := P_{j-1}(x, y)$ and go to next iteration of the loop
   - (c) if $\deg_x(P_{j-1}) \geq 2^{t-(j-1)}$, continue this iteration
   - (d) write $P_{j-1}(x, y) = x^{2^{t-j+1}} P_{j-1}^{(1)}(x, y) + P_{j-1}^{(0)}(x, y)$ with $\deg_x(P_{j-1}^{(1)}) \leq \deg_x(P_{j-1}) - 2^{t-j+1}$ and $\deg_y(P_{j-1}^{(0)}) < 2^{t-j+1}$
   - (e) replace $x^{2^{t-j+1}}$ with $R_{t-\kappa+j-1}(x, y)$ in $P_{j-1}(x, y)$ to obtain $P_{j-1}(x, y) := P_{j-1}^{(1)}(x, y) + P_{j-1}^{(0)}(x, y)$ with $\deg_x(P_{j-1}^{(1)}) \leq \deg_x(P_{j-1}) - 2^{t-j+1} + 2^{\kappa-1}$
   - (f) write $P_{j-1}'(x, y) = x^{2^t-j+1} P_{j-1}'^{(1)}(x, y) + P_{j-1}'^{(0)}(x, y)$ with $\deg_x(P_{j-1}'^{(1)}) \leq \deg_x(P_{j-1}) - 2^{t-j+2} + 2^{\kappa-1}$ and $\deg_y(P_{j-1}'^{(0)}) < 2^{t-j+1}$
   - (g) replace $x^{2^{t-j+1}}$ with $R_{t-\kappa+j-1}(x, y)$ in $P_{j-1}'(x, y)$ to obtain $P_j(x, y)$ with $\deg_x(P_j) < 2^{t-j+1}$
8. output $Q(x, y) := P_{t-\kappa+1}(x, y)$

notes:
- Step 4 and Step 5 construct a $(t - \kappa + 1)$-line table, and in each line of the table there is a polynomial with at most $(t - \kappa + 1)$ $y$-monomials and $\kappa$ $x$-monomials for substitution of a larger power of $x$ (specifically, the $i$-th line is for substituting $x^{2^{i+1}}$)
- in each iteration of the loop in Step 7 we substitute a large power of $x$ twice, and these two substitutions will jointly halve the degree of the polynomial, and that is why we only need few iterations (i.e., $t - \kappa + 1$ iterations)
C Complexity Analysis

We carefully analyze the query complexity, randomness complexity, and proof length complexity of \((P_{sACSP}, V_{sACSP})\), which is the PCP system for sACSP discussed in Section 7;\(^{30}\) the resulting expressions for the three complexity measures can be easily evaluated numerically for any given set of parameters. Recall that pseudocode listings for the PCP system \((P_{sACSP}, V_{sACSP})\) are given in Appendix B.

In this section, we proceed “bottom-up”, analyzing each module in Figure 1, one prover-verifier pair at a time. Throughout, we fix a choice of integer parameters \((\eta, \kappa_0, \gamma, \mu)\) satisfying Equation 8 in Theorem 10.3.

C.1 Complexity Analysis of \(P_{RS,=}\) and \(V_{RS,=}\)

The PCPP prover \(P_{RS,=}\) is described in Algorithm 7 and the (strong) PCPP verifier \(V_{RS,=}\) is described in Algorithm 16.

**Lemma C.1** (Complexity Parameters for \(P_{RS,=}\) and \(V_{RS,=}\)). The following equations hold:

\[
\begin{align*}
\text{query}_{RS,=}(\ell, \kappa) &\leq 2^{\kappa_0} , \\
\text{rand}_{RS,=}(\ell, \kappa) &\leq \kappa + (\mu + 2) \log(2\kappa) , \\
\text{length}_{RS,=}(\ell, \kappa) &\leq 2\kappa^{1+\max\{-\gamma+\mu+1,\gamma\}} .
\end{align*}
\]

**Proof.** As was already remarked in [BSS08, Propistion 6.8], it is easy to see that the query complexity is as follows:

\[
\text{query}_{RS,=}(\ell, \kappa) = \begin{cases} 
2^\kappa & \text{if } \kappa \leq \kappa_0 \\
0 & \text{if } \kappa > \kappa_0
\end{cases} \leq 2^{\kappa_0} .
\]

Next, as was already remarked in [BSS08, Proposition 6.8] (and then in further detail in [Bha05, Sec. 2.3.1]), the randomness complexity satisfies the recursion from Lemma C.9 (after appropriately generalizing it to our more general constructions), and our lemma tells us that we can upper bound it follows:

\[
\text{rand}_{RS,=}(\ell, \kappa) \leq \begin{cases} 
0 & \text{if } \kappa \leq \kappa_0 \\
\kappa + (\mu + 2) \log(\kappa - 2 \max\{-\gamma + \mu + 1, \gamma\}) & \text{if } \kappa > \kappa_0
\end{cases} \leq \kappa + (\mu + 2) \log(2\kappa) .
\]

Finally, as was already remarked in [BSS08, Proposition 6.8] (and then in further detail in [Bha05, Sec. 2.2.2]), the proof length complexity satisfies the recursion from Lemma C.10 (after appropriately generalizing it to our more general constructions), and our lemma tells us that we can upper bound it as follows:

\[
\text{length}_{RS,=}(\ell, \kappa) \leq 2\kappa^{1+\max\{-\gamma+\mu+1,\gamma\}} .
\]

Of course, if one wishes to numerically evaluate \(\text{rand}_{RS,=}(\ell, \kappa)\) or \(\text{length}_{RS,=}(\ell, \kappa)\), using the recursive function (in Lemma C.9 or Lemma C.10 respectively) will give the exact value. (Though our bounds are quite tight.)

\[^{30}\text{We do not discuss here the prover and verifier time and space complexities; indeed, a detailed complexity analysis of such performance measures (e.g., by paying close attention to multiplicative constants) does not seem feasible and is ultimately not fruitful — after all, concrete time and space requirements of a prover and verifier are best studied through a code implementation, which we leave to future work.}\]
C.2 Complexity Analysis of $P_{\text{rs},<}$ and $V_{\text{rs},<}$

The PCPP prover $P_{\text{rs},<}$ is described in Algorithm 6 and the (strong) PCPP verifier $V_{\text{rs},<}$ is described in Algorithm 15.

Lemma C.2 (Complexity Parameters for $P_{\text{rs},<}$ and $V_{\text{rs},<}$). The following equations hold:

\begin{align*}
\text{query}_{\text{rs},<}(\ell, \kappa, d) &= 2 \cdot \text{query}_{\text{rs},=}(\ell, \kappa), \\
\text{rand}_{\text{rs},<}(\ell, \kappa, d) &= \text{rand}_{\text{rs},=}(\ell, \kappa), \\
\text{length}_{\text{rs},<}(\ell, \kappa, d) &= 2 \cdot \text{length}_{\text{rs},=}(\ell, \kappa).
\end{align*}

Proof. Immediate from the construction of $P_{\text{rs},<}$ and $V_{\text{rs},<}$. \hfill \Box

C.3 Complexity Analysis of $P_{\text{rs},>}$ and $V_{\text{rs},>}$

The PCPP prover $P_{\text{rs},>}$ is described in Algorithm 5 and the (strong) PCPP verifier $V_{\text{rs},>}$ is described in Algorithm 14. Recall that $d_{\kappa, \eta} := 2^\kappa / 2^\eta - 1$.

Lemma C.3 (Complexity Parameters for $P_{\text{rs},>}$ and $V_{\text{rs},>}$). The following equations hold:

\begin{align*}
\text{query}_{\text{rs},>}(\ell, \kappa, d) &= m_{\kappa, \eta, d} \cdot \text{query}_{\text{rs},=}(\ell, \kappa) + 1_{\kappa, \eta, d} \cdot \text{query}_{\text{rs},<}(\ell, \kappa, d - m_{\kappa, \eta, d}(d_{\kappa, \eta} + 1)) + m_{\kappa, \eta, d} + 1_{\kappa, \eta, d} + 1, \\
\text{rand}_{\text{rs},>}(\ell, \kappa, d) &= \max \left\{ \text{rand}_{\text{rs},=}(\ell, \kappa), 1_{\kappa, \eta, d} \cdot \text{rand}_{\text{rs},<}(\ell, \kappa, d - m_{\kappa, \eta, d}(d_{\kappa, \eta} + 1)) \right\}, \\
\text{length}_{\text{rs},>}(\ell, \kappa, d) &= m_{\kappa, \eta, d} \cdot (2^\kappa + \text{length}_{\text{rs},=}(\ell, \kappa) + 1_{\kappa, \eta, d} \cdot (2^\kappa + \text{length}_{\text{rs},<}(\ell, \kappa, d - m_{\kappa, \eta, d}(d_{\kappa, \eta} + 1)))) + 1_{\kappa, \eta, d} := 1 \text{ if } (d + 1) > m_{\kappa, \eta, d}(d_{\kappa, \eta} + 1) \text{ and } 1_{\kappa, \eta, d} := 0 \text{ otherwise.}
\end{align*}

Proof. Immediate from the construction of $P_{\text{rs},>}$ and $V_{\text{rs},>}$. \hfill \Box

C.4 Complexity Analysis of $P_{\text{rs}}$ and $V_{\text{rs}}$

The PCPP prover $P_{\text{rs}}$ is described in Algorithm 4 and the (strong) PCPP verifier $V_{\text{rs}}$ is described in Algorithm 13.

Lemma C.4 (Complexity Parameters for $P_{\text{rs}}$ and $V_{\text{rs}}$). The following equations hold:

\begin{align*}
\text{query}_{\text{rs}}(\ell, \kappa, d) &= \begin{cases} 
\text{query}_{\text{rs},<}(\ell, \kappa, d) & \text{if } d < d_{\kappa, \eta} \\
\text{query}_{\text{rs},=}(\ell, \kappa) & \text{if } d = d_{\kappa, \eta} \\
\text{query}_{\text{rs},>}(\ell, \kappa, d) & \text{if } d > d_{\kappa, \eta}
\end{cases}, \\
\text{rand}_{\text{rs}}(\ell, \kappa, d) &= \begin{cases} 
\text{rand}_{\text{rs},<}(\ell, \kappa, d) & \text{if } d < d_{\kappa, \eta} \\
\text{rand}_{\text{rs},=}(\ell, \kappa) & \text{if } d = d_{\kappa, \eta} \\
\text{rand}_{\text{rs},>}(\ell, \kappa, d) & \text{if } d > d_{\kappa, \eta}
\end{cases}, \\
\text{length}_{\text{rs}}(\ell, \kappa, d) &= \begin{cases} 
\text{length}_{\text{rs},<}(\ell, \kappa, d) & \text{if } d < d_{\kappa, \eta} \\
\text{length}_{\text{rs},=}(\ell, \kappa) & \text{if } d = d_{\kappa, \eta} \\
\text{length}_{\text{rs},>}(\ell, \kappa, d) & \text{if } d > d_{\kappa, \eta}
\end{cases}.
\end{align*}

Proof. The prover $P_{\text{rs}}$ simply calls $P_{\text{rs},<}$, $P_{\text{rs},=}$, or $P_{\text{rs},>}$, depending on whether the input degree $d$ is less than, equal to, or greater than $d_{\kappa, \eta} := 2^\kappa / 2^\eta - 1$; similarly for $V_{\text{rs}}$.\footnote{\text{Though if } \kappa \text{ no larger than } \eta \text{, then } V_{\text{rs}} \text{ will directly test the degree of the implicit input. We do not include this case in the complexity analysis, because } \eta \text{ is a very small constant, and we will never be interested in inputs of such a small dimension!}}

128
C.5 Complexity Analysis of $P_{VRS}$ and $V_{VRS}$

The PCPP prover $P_{VRS}$ is described in Algorithm 3 and the (strong) PCPP verifier $V_{VRS}$ is described in Algorithm 12.

**Lemma C.5** (Complexity Parameters for $P_{VRS}$ and $V_{VRS}$). The following equations hold:
\[
\begin{align*}
\text{query}_{VRS}(\ell, \kappa, \lambda, d) &= \text{query}_{RS}(\ell, \kappa, d - 2^\lambda) + 2, \\
\text{rand}_{VRS}(\ell, \kappa, \lambda, d) &= \max\{\text{rand}_{RS}(\ell, \kappa, d - 2^\lambda), \kappa\}, \\
\text{length}_{VRS}(\ell, \kappa, \lambda, d) &= 2^\kappa + \text{length}_{RS}(\ell, \kappa, d - 2^\lambda),
\end{align*}
\]

**Proof.** Immediate from the construction of $P_{VRS}$ and $V_{VRS}$. \hfill \square

C.6 Complexity Analysis of $V_{aRS}$ and $V_{aVRS}$

The (“weak”) PCPP verifier $V_{aRS}$ is described in Algorithm 11; its corresponding prover is simply the PCPP prover $P_{RS}$ from Algorithm 4.

**Lemma C.6** (Complexity Parameters for $V_{aRS}$). The following equations hold:
\[
\begin{align*}
\text{query}_{aRS}(\ell, \kappa, d, \delta, s') &= m_{s_{RS}, \delta, s'}(n) \cdot \text{query}_{RS}(\ell, \kappa, d), \\
\text{rand}_{aRS}(\ell, \kappa, d, \delta, s') &= m_{s_{RS}, \delta, s'}(n) \cdot \text{rand}_{RS}(\ell, \kappa, d).
\end{align*}
\]

**Proof.** Observe that $V_{aRS}$ simply performs naive sequential repetition on $V_{RS}$. Hence, by Remark 10.2, in order to obtain a “weak” PCPP with proximity parameter $\delta$ and target soundness $s'$ (both given as input to $V_{aRS}$), the number of repetitions is:
\[
m_{s_{RS}, \delta, s'}(n) = \left\lceil \frac{\log(1 - s')}{s_{RS}(\delta, n)} \right\rceil.
\]

where $n = 2^\kappa$ and $s_{RS}$ is the soundness of $V_{RS}$. (Recall that Theorem 10.1 gives a lower bound on $s_{RS}$.)

The query complexity and randomness complexity thus simply increase by the multiplicative factor $m_{s_{RS}, \delta, s'}(n)$. \hfill \square

The (“weak”) PCPP verifier $V_{aVRS}$ is described in Algorithm 10; its corresponding prover is simply the PCPP prover $P_{VRS}$ from Algorithm 3.

**Lemma C.7** (Complexity Parameters for $V_{aVRS}$). The following equations hold:
\[
\begin{align*}
\text{query}_{aVRS}(\ell, \kappa, \lambda, d, \delta, s') &= m_{s_{VRS}, \delta, s'}(n) \cdot \text{query}_{VRS}(\ell, \kappa, \lambda, d), \\
\text{rand}_{aVRS}(\ell, \kappa, \lambda, d, \delta, s') &= m_{s_{VRS}, \delta, s'}(n) \cdot \text{rand}_{VRS}(\ell, \kappa, \lambda, d).
\end{align*}
\]

**Proof.** Observe that $V_{aVRS}$ simply performs naive sequential repetition on $V_{VRS}$. Hence, by Remark 10.2, in order to obtain a “weak” PCPP with proximity parameter $\delta$ and target soundness $s'$ (both given as input to $V_{aVRS}$), the number of repetitions is:
\[
m_{s_{VRS}, \delta, s'}(n) = \left\lceil \frac{\log(1 - s')}{s_{VRS}(\delta, n)} \right\rceil.
\]

where $n = 2^\kappa$ and $s_{VRS}$ is the soundness of $V_{VRS}$. (Recall that Theorem 10.1 gives a lower bound on $s_{VRS}$.)

The query complexity and randomness complexity thus simply increase by the multiplicative factor $m_{s_{VRS}, \delta, s'}(n)$. \hfill \square
C.7 Complexity Analysis of $P_{\text{ACSP}}$ and $V_{\text{ACSP}}$

The prover $P_{\text{ACSP}}$ is described in Algorithm 2 (and also in Construction 7.3) and the verifier $V_{\text{ACSP}}$ is described in Algorithm 9 (and also in Construction 7.5).

**Lemma C.8** (Complexity Parameters for $P_{\text{ACSP}}$ and $V_{\text{ACSP}}$). The following equations hold:

- $\text{query}_{\text{ACSP}}(x,t) = \text{query}_{\text{ARS}}(f(t), f(t), 2^{m_H(t)} - 1, \frac{1}{8c_N(t) \cdot \frac{1}{2}}) + \text{query}_{\text{AVRS}}(f(t), f(t), m_H(t), d, \frac{1}{8}, \frac{1}{2}) + (c_N(t) + 1) + \text{query}_{\text{AVRS}}(f(t), f(t), \log |x|, 2^{m_H(t)} - 1, \frac{1}{8c_N(t) \cdot \frac{1}{2}})$,

- $\text{rand}_{\text{ACSP}}(x,t) = \max \left\{ \text{rand}_{\text{ARS}}(f(t), f(t), 2^{m_H(t)} - 1, \frac{1}{8c_N(t) \cdot \frac{1}{2}}), \text{rand}_{\text{AVRS}}(f(t), f(t), m_H(t), d, \frac{1}{8}, \frac{1}{2}), f(t), \text{rand}_{\text{AVRS}}(f(t), f(t), \log |x|, 2^{m_H(t)} - 1, \frac{1}{8c_N(t) \cdot \frac{1}{2}}) \right\}$,

- $\text{length}_{\text{ACSP}}(x,t) = 2^f(t) + \text{length}_{\text{ARS}}(f(t), f(t), 2^{m_H(t)} - 1, \frac{1}{8c_N(t) \cdot \frac{1}{2}}) + 2^f(t) + \text{length}_{\text{AVRS}}(f(t), f(t), m_H(t), d, \frac{1}{8}, \frac{1}{2}) + \text{length}_{\text{AVRS}}(f(t), f(t), \log |x|, 2^{m_H(t)} - 1, \frac{1}{8c_N(t) \cdot \frac{1}{2}})$,

where $d := \deg(P(x, x^{(2^{m_H(t)} - 1)} \cdot \deg(N_{t, 1}), \ldots, x^{(2^{m_H(t)} - 1)} \cdot \deg(N_{t, c_N(t)})))$.

*Proof.* Immediate from the construction of $P_{\text{ACSP}}$ and $V_{\text{ACSP}}$. \hfill \square

C.8 Solving Recursions

We deduce an upper bound for two recursive functions that arise in Appendix C.1: respectively, the upper bounds are on the recursive function giving the amount of randomness used by $V_{\text{RS}_{\text{ARS}}}$. (Lemma C.9) and the recursive function giving the length of the proximity proof generated by $P_{\text{RS}_{\text{ARS}}}$. (Lemma C.10).

**Lemma C.9.** The recursion

$$r(\kappa) = \begin{cases} 0 & \text{if } \kappa \leq \kappa_0 \\ 1 + \max \left\{ \left[ \frac{\kappa}{2} \right] + \gamma + r \left( \left[ \frac{\kappa}{2} \right] - \gamma + \mu + 1 \right), \left[ \frac{\kappa}{2} \right] - \gamma + \mu + r \left( \left[ \frac{\kappa}{2} \right] + \gamma \right) \right\} & \text{if } \kappa > \kappa_0 \end{cases}$$

(29)

is upper bounded by the function

$$\tilde{r}(\kappa) = \begin{cases} 0 & \text{if } \kappa \leq \kappa_0 \\ \kappa + (\mu + 2) \log (\kappa - 2 \max\{-\gamma + \mu + 1, \gamma\}) & \text{if } \kappa > \kappa_0 \end{cases} .$$

*Proof.* For $\kappa \in \{1, \ldots, \kappa_0\}$, the equality follows immediately. The parameter constraints from Equation 8 imply that $\tilde{r}(\kappa)$ is well-defined for $\kappa > \kappa_0$:

$$\frac{k}{2} \geq \frac{\kappa_0 + 1}{2} \geq \left\lfloor \frac{\kappa_0 + 1}{2} \right\rfloor \geq \gamma + 1 \geq \gamma + \frac{1}{2}$$

and
\[
\frac{k}{2} \geq \frac{\kappa_0 + 1}{2} \geq \left\lfloor \frac{\kappa_0 + 1}{2} \right\rfloor - \frac{1}{2} \geq -\gamma + \mu + 2 - \frac{1}{2} = -\gamma + \mu + 1 + \frac{1}{2},
\]
so that \(\kappa - 2 \cdot \max\{-\gamma + \mu + 1, \gamma\} \geq 1 > 0\). Also, it will be useful to also derive the following inequalities (also implied by Equation 8):
\[
\kappa - \left\lfloor \frac{\kappa}{2} \right\rfloor + \gamma + 1 = \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma - 1 \geq \left\lfloor \frac{\kappa_0 + 1}{2} \right\rfloor - \gamma - 1 \geq 0 \quad \text{and}
\]
\[
\kappa - \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 1 = \left\lfloor \frac{\kappa}{2} \right\rfloor + \gamma - \mu - 1 \geq 1 \geq 0.
\]
Finally, we observe that, for every two \(\kappa\) and \(c\) with \(\kappa \geq 2c\):
\[
\log \left(\frac{\kappa}{2} - c\right) \leq \log \left(\frac{\kappa}{2} - c\right) = \log(\kappa - 2c) - 1 \quad \text{and}
\]
\[
\log \left(\frac{\kappa}{2} - c\right) \leq \log \left(\frac{\kappa}{2} - c + 1\right) = \log(\kappa - 2c + 2) - 1.
\]
Now we go back to the rest of the proof. For \(\kappa > \kappa_0\), we distinguish between four cases:

- **Case 1:** \(\kappa\) is such that \([\kappa/2] - \gamma + \mu + 1 \leq \kappa_0\) and \([\kappa/2] + \gamma \leq \kappa_0\). By Equation 29, the defining equation for \(r(\kappa)\), we get:
  \[
  r(\kappa) = 1 + \max \left\{ \left\lfloor \frac{\kappa}{2} \right\rfloor + \gamma + r \left( \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 1 \right), \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + r \left( \left\lfloor \frac{\kappa}{2} \right\rfloor + \gamma \right) \right\}
  \]
  \[
  = 1 + \max \left\{ \left\lfloor \frac{\kappa}{2} \right\rfloor + \gamma + 0, \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 0 \right\}
  \]
  \[
  \leq \kappa
  \]
  \[
  \leq \kappa + (\mu + 2) \log(\kappa - 2 \max\{-\gamma + \mu + 1, \gamma\})
  \]

- **Case 2:** \(\kappa\) is such that \([\kappa/2] - \gamma + \mu + 1 > \kappa_0\) and \([\kappa/2] + \gamma \leq \kappa_0\). By Equation 29, the defining equation for \(r(\kappa)\), we get:
  \[
  r(\kappa) = 1 + \max \left\{ \left\lfloor \frac{\kappa}{2} \right\rfloor + \gamma + r \left( \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 1 \right), \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + r \left( \left\lfloor \frac{\kappa}{2} \right\rfloor + \gamma \right) \right\}
  \]
  \[
  \leq 1 + \max \left\{ \left\lfloor \frac{\kappa}{2} \right\rfloor + \gamma + \left( \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 1 + (\mu + 2) \log \left( \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 1 - 2 \max\{-\gamma + \mu + 1, \gamma\} \right) \right), \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 0 \right\}
  \]
  \[
  \leq 1 + \max \left\{ \kappa + \mu + 1 + (\mu + 2) \log \left( \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 1 - 2 \max\{-\gamma + \mu + 1, \gamma\} \right), \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu \right\}
  \]
  \[
  \leq 1 + \max \left\{ \kappa + \mu + 1 + (\mu + 2) \log \left( \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 1 - \max\{-\gamma + \mu + 1, \gamma\} \right), \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu \right\}
  \]
  \[
  \leq \max \left\{ \kappa + (\mu + 2) \log(\kappa - 2 \max\{-\gamma + \mu + 1, \gamma\}), \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 1 \right\}
  \]
  \[
  = \kappa + (\mu + 2) \log(\kappa - 2 \max\{-\gamma + \mu + 1, \gamma\}).
  \]

- **Case 3:** \(\kappa\) is such that \([\kappa/2] - \gamma + \mu + 1 \leq \kappa_0\) and \([\kappa/2] + \gamma > \kappa_0\). By Equation 29, the defining equation for \(r(\kappa)\), we get:
  \[
  r(\kappa) = 1 + \max \left\{ \left\lfloor \frac{\kappa}{2} \right\rfloor + \gamma + r \left( \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + 1 \right), \left\lfloor \frac{\kappa}{2} \right\rfloor - \gamma + \mu + r \left( \left\lfloor \frac{\kappa}{2} \right\rfloor + \gamma \right) \right\}
  \]

131
Lemma C.10. The recursive function

\[ r(\kappa) = \begin{cases} 
0 & \text{if } \kappa \leq \kappa_0 \\
2^{\lceil \kappa/2 \rceil} + \gamma \cdot 2^{\lceil \kappa/2 \rceil - \gamma + \mu + 1} + 2^{\lceil \kappa/2 \rceil} \cdot r(\lceil \kappa/2 \rceil - \gamma + \mu + 1) + 2^{\lceil \kappa/2 \rceil} \cdot r(\lceil \kappa/2 \rceil + \gamma) & \text{if } \kappa > \kappa_0
\end{cases} \]

is upper bounded by the function

\[ \tilde{r}(\kappa) = 2^\kappa \cdot 1^{\max\{-\gamma + \mu + 1, \gamma\}}. \]

Proof. Let \( \tilde{s}(\kappa) \) be a generic function of \( \kappa \in \mathbb{N} \). We derive constraints on \( \tilde{s}(\kappa) \) such that \( r(\kappa) \leq 2^\kappa \cdot \tilde{s}(\kappa) \). For \( \kappa \in \{1, \ldots, \kappa_0\} \), the inequality \( r(\kappa) \leq 2^\kappa \cdot \tilde{s}(\kappa) \) follows as long as \( \tilde{s}(\kappa) \) is non-negative on \( \{1, \ldots, \kappa_0\} \). For \( \kappa > \kappa_0 \), we distinguish between four cases:

- **Case 1:** \( \kappa \) is such that \( \lceil \kappa/2 \rceil - \gamma + \mu + 1 > \kappa_0 \) and \( \lceil \kappa/2 \rceil + \gamma \leq \kappa_0 \). By Equation 30, the defining equation for \( r(\kappa) \), we get:

\[
\begin{align*}
   r(\kappa) &= 2^{\mu^0} \cdot 2^\kappa + 2^{\lceil \kappa/2 \rceil + \gamma} \cdot r(\lceil \kappa/2 \rceil - \gamma + \mu + 1) + 2^{\lceil \kappa/2 \rceil} \cdot r(\lceil \kappa/2 \rceil + \gamma) \\
   &\leq 2^{\mu^0} \cdot 2^\kappa + 2^{\lceil \kappa/2 \rceil + \gamma} \cdot 0 + 2^{\lceil \kappa/2 \rceil} \cdot 2^{\mu^0} \cdot 0 \\
   &= 2^{\mu^0} \cdot 2^\kappa \\
   &\leq 2^\kappa \cdot \tilde{s}(\kappa),
\end{align*}
\]

where the first inequality follows by the inductive hypothesis and the last inequality is a constraint for \( \tilde{s} \).

- **Case 2:** \( \kappa \) is such that \( \lceil \kappa/2 \rceil - \gamma + \mu + 1 > \kappa_0 \) and \( \lceil \kappa/2 \rceil + \gamma > \kappa_0 \). By Equation 30, the defining equation for \( r(\kappa) \), we get:

\[
\begin{align*}
   r(\kappa) &= 2^{\mu^0} \cdot 2^\kappa + 2^{\lceil \kappa/2 \rceil + \gamma} \cdot r(\lceil \kappa/2 \rceil - \gamma + \mu + 1) + 2^{\lceil \kappa/2 \rceil} \cdot r(\lceil \kappa/2 \rceil + \gamma) \\
   &\leq 2^{\mu^0} \cdot 2^\kappa + 2^{\lceil \kappa/2 \rceil + \gamma} \cdot \left(2^{\lceil \kappa/2 \rceil - \gamma + \mu + 1} \cdot \tilde{s}(\lceil \kappa/2 \rceil - \gamma + \mu + 1)\right) + 2^{\lceil \kappa/2 \rceil} \cdot 0
\end{align*}
\]

\[ = \kappa + (\mu + 2) \log (\kappa - 2 \max\{-\gamma + \mu + 1, \gamma\}) \]
\[
= 2^{\mu+1} \cdot 2^\kappa + 2^{\mu+1} \cdot 2^\kappa \cdot \tilde{s}([\kappa/2] - \gamma + \mu + 1)
= 2^\kappa \cdot (2^{\mu+1} + 2^{\mu+1} \cdot \tilde{s}([\kappa/2] - \gamma + \mu + 1))
\leq 2^\kappa \cdot \tilde{s}(\kappa),
\]
where the first inequality follows by the inductive hypothesis and the last inequality is a constraint (additional to the other one that we already derived) for \(\tilde{s}\).

**Case 3:** \(\kappa\) is such that \([\kappa/2] - \gamma + \mu + 1 \leq \kappa_0\) and \([\kappa/2] + \gamma > \kappa_0\). By Equation 30, the defining equation for \(r(\kappa)\), we get:

\[
\begin{align*}
    r(\kappa) &= 2^{\mu+1} \cdot 2^\kappa + 2^{[\kappa/2]+\gamma} \cdot r([\kappa/2] - \gamma + \mu + 1) + 2^{[\kappa/2]-\gamma+\mu} \cdot r([\kappa/2] + \gamma) \\
    &\leq 2^{\mu+1} \cdot 2^\kappa + 2^{[\kappa/2]+\gamma} \cdot \left(2^{[\kappa/2]-\gamma+\mu+1} \cdot \tilde{s}([\kappa/2] - \gamma + \mu + 1)\right) \\
    & \quad + 2^{[\kappa/2]-\gamma+\mu} \cdot \left(2^{[\kappa/2]+\gamma} \cdot \tilde{s}([\kappa/2] + \gamma)\right) \\
    &= 2^{\mu+1} \cdot 2^\kappa + 2^{\mu+1} \cdot 2^\kappa \cdot \tilde{s}([\kappa/2] - \gamma + \mu + 1) + 2^\mu \cdot 2^\kappa \cdot \tilde{s}([\kappa/2] + \gamma) \\
    &= 2^\kappa \cdot (2^{\mu+1} + 2^{\mu+1} \cdot \tilde{s}([\kappa/2] - \gamma + \mu + 1) + 2^\mu \cdot \tilde{s}([\kappa/2] + \gamma)) \\
    &\leq 2^\kappa \cdot \tilde{s}(\kappa),
\end{align*}
\]
where the first inequality follows by the inductive hypothesis and the last inequality is a constraint (additional to the other two that we already derived) for \(\tilde{s}\).

**Case 4:** \(\kappa\) is such that \([\kappa/2] - \gamma + \mu + 1 > \kappa_0\) and \([\kappa/2] + \gamma > \kappa_0\). By Equation 30, the defining equation for \(r(\kappa)\), we get:

\[
\begin{align*}
    r(\kappa) &= 2^{\mu+1} \cdot 2^\kappa + 2^{[\kappa/2]+\gamma} \cdot r([\kappa/2] - \gamma + \mu + 1) + 2^{[\kappa/2]-\gamma+\mu} \cdot r([\kappa/2] + \gamma) \\
    &\leq 2^{\mu+1} \cdot 2^\kappa + 2^{[\kappa/2]+\gamma} \cdot \left(2^{[\kappa/2]-\gamma+\mu+1} \cdot \tilde{s}([\kappa/2] - \gamma + \mu + 1)\right) \\
    & \quad + 2^{[\kappa/2]-\gamma+\mu} \cdot \left(2^{[\kappa/2]+\gamma} \cdot \tilde{s}([\kappa/2] + \gamma)\right) \\
    &= 2^{\mu+1} \cdot 2^\kappa + 2^{\mu+1} \cdot 2^\kappa \cdot \tilde{s}([\kappa/2] - \gamma + \mu + 1) + 2^\mu \cdot 2^\kappa \cdot \tilde{s}([\kappa/2] + \gamma) \\
    &= 2^\kappa \cdot (2^{\mu+1} + 2^{\mu+1} \cdot \tilde{s}([\kappa/2] - \gamma + \mu + 1) + 2^\mu \cdot \tilde{s}([\kappa/2] + \gamma)) \\
    &\leq 2^\kappa \cdot \tilde{s}(\kappa),
\end{align*}
\]
where the first inequality follows by the inductive hypothesis and the last inequality is a constraint (additional to the other three that we already derived) for \(\tilde{s}\).

Overall, we require that

\[
\tilde{s}(\kappa) \begin{cases} 
0 & \text{if } \kappa \leq \kappa_0 \\
2^{\mu+1} & \text{if Case 1} \\
2^{\mu+1} + 2^{\mu+1} \cdot \tilde{s}([\kappa/2] - \gamma + \mu + 1) & \text{if Case 2} \\
2^{\mu+1} + 2^{\mu+1} \cdot \tilde{s}([\kappa/2] + \gamma) & \text{if Case 3} \\
2^{\mu+1} + 2^{\mu+1} \cdot \tilde{s}([\kappa/2] - \gamma + \mu + 1) + 2^\mu \cdot \tilde{s}([\kappa/2] + \gamma) & \text{if Case 4}
\end{cases}
\]

By inspection, \(\tilde{s}(\kappa) \overset{\text{def}}{=} 2^{1+\max\{-\gamma+\mu+1, \gamma\}}\) works for all \(\kappa \in \mathbb{N}\). \(\square\)
