

# On the Relationship between Statistical Zero-Knowledge and Statistical Randomized Encodings

Benny Applebaum<sup>\*</sup>

Pavel Raykov\*

### Abstract

Statistical Zero-knowledge proofs (Goldwasser, Micali and Rackoff, SICOMP 1989) allow a computationally-unbounded server to convince a computationally-limited client that an input x is in a language  $\Pi$  without revealing any additional information about x that the client cannot compute by herself. Randomized encoding (RE) of functions (Ishai and Kushilevitz, FOCS 2000) allows a computationally-limited client to publish a single (randomized) message, Enc(x), from which the server learns whether x is in  $\Pi$  and nothing else.

It is known that SRE, the class of problems that admit statistically private randomized encoding with polynomial-time client and computationally-unbounded server, is contained in the class SZK of problems that have statistical zero-knowledge proof. However, the exact relation between these two classes, and, in particular, the possibility of equivalence was left as an open problem.

In this paper, we explore the relationship between SRE and SZK, and derive the following results:

- In a non-uniform setting, statistical randomized encoding with one-side privacy  $(\mathcal{IRE})$  is equivalent to non-interactive statistical zero-knowledge ( $\mathcal{NISZK}$ ). These variants were studied in the past as natural relaxation/strengthening of the original notions. Our theorem shows that proving  $\mathcal{SRE} = \mathcal{SZK}$  is equivalent to showing that  $\mathcal{IRE} = \mathcal{SRE}$  and  $\mathcal{SZK} = \mathcal{NISZK}$ . The latter is a well-known open problem (Goldreich, Sahai, Vadhan, CRYPTO 1999).
- If SRE is non-trivial (not in BPP), then infinitely-often one-way functions exist. The analog hypothesis for SZK yields only *auxiliary-input* one-way functions (Ostrovsky, Structure in Complexity Theory, 1991), which is believed to be a significantly weaker implication.
- If there exists an average-case hard language with *perfect randomized encoding*, then collision-resistance hash functions (CRH) exist. Again, a similar assumption for SZK implies only constant-round statistically-hiding commitments, a primitive which seems weaker than CRH.

We believe that our results sharpen the relationship between SRE and SZK and illuminates the core differences between these two classes.

## 1 Introduction

Consider a "computationally-weak" client, Alice, which holds an input  $x \in \{0, 1\}^n$  to a language, or promise problem,  $\Pi$  which is beyond her computational power. We will be interested in the following two related scenarios.

- Alice contacts a computationally-strong server Bob, and asks him to prove that x is a yesinstance of  $\Pi$ . The server wishes to do so without revealing any additional information about x that Alice cannot compute by herself. That is, we are interested in an interactive proof system in which, for every yes-instance, the client is able to simulate her view without any interaction with the server.
- Alice would like to send to the server Bob a single (randomized) message Enc(x) which allows Bob to tell whether x is a yes-instance or a no-instance but hides any other information about x. That is, the message Enc(x) should be *private* in the sense that all yes-instances (resp., no-instances) are mapped by Enc(x) to the same universal yes-distribution  $Sim_{YES}$  (resp., no-distribution  $Sim_{NO}$ ); In addition, Enc(x) should be *correct* (i.e., it should be possible to decode membership in  $\Pi$ ) and so the yes-distribution is required to be statistically-far from the no-distribution.

The first setting is captured by the notion of *zero-knowledge* (ZK) proofs [GMR89], while the second is captured by the notion of *randomized encoding* (RE) of functions [IK00, AIK04]. In this paper, we model the client as a polynomial-time machine, the server as a computationally-unbounded party, and ask for information-theoretic security.<sup>1</sup> Problems that admit such a statistical zero-knowledge proofs (resp., such statistical randomized encodings) give rise to the complexity class SZK (resp., SRE).

The class SZK and its variants were extensively studied and we have relatively rich insights about its power and structure including non-trivial upper-bounds (e.g.,  $SZK \subseteq AM \cap \text{co-}AM$  [AH87]), complete problems [SV03, GV99], and closure properties [Oka00, Vad99]. Unfortunately, the status of SRE is very different. Although randomized encoding are extensively used in cryptography (see the surveys [App11, Ish13]), the class SRE was left relatively unexplored. The main known result (observed in [App14]) is that

$$SRE \subseteq SZK.$$

That is, a statistical randomized encoding for a problem II can be transformed into a statistical zero knowledge proof system for the same problem. The exact relation between SRE and SZK, and, in particular, the intriguing possibility that these two classes are actually equivalent was left as an open problem. This question was recently addressed by Agrawal, Ishai, Khurana, and Paskin-Cherniavsky [AIKP15] who provided an oracle separation between the two classes, in addition to candidates for problems in SRE that are not solvable in (non-uniform) polynomial-time. As usual, an oracle separation tells us that equivalence cannot be established via relativized techniques, and so it essentially addresses the *proof of equivalence* (or technical barriers against it). However, such separations tell us very little on the statement itself (SRE = SZK) and its potential implications on the landscape of computational complexity.

<sup>&</sup>lt;sup>1</sup>The literature contains many other natural choices for security (e.g., computational [AIK05]) and efficiency (e.g., client with low parallel complexity and polynomial-time server [AIK04]). Following Agrawal, Ishai, Khurana, and Paskin-Cherniavet [AIKP15], we view the current choice as a natural starting point for a complexity-theoretic treatment.

### 1.1 Our Results

In this paper, we continue the complexity theoretic study of SRE, as advocated by [AIKP15], and further explore the exact relationship between SRE and SZK. We study variants of these classes, prove their equivalence, and sharpen the difference between SRE and SZK. We also point out several interesting complexity-theoretic implications of an equivalence between SRE and SZK. Overall, we believe that our results shed light on the causes for which SZK is (seemingly) more powerful than SRE.

### 1.1.1 Non-interactive ZK is equivalent to Semi-private RE

Zero-knowledge proofs differ from randomized-encoding in many aspects. Most notably, the flow of information is reversed (Server-to-Client for ZK-proofs vs. Client-to-Sever for encodings). Let us ignore this major difference and focus on two seemingly less important syntactic differences. First, recall that REs are non-interactive while zero-knowledge proofs are allowed to use interaction. Secondly, the privacy condition of REs should hold for both yes and no instances, whereas the ZK condition is defined only with respect to yes-instances. In an attempt to make a "fair" comparison between these two notions, we consider *non-interactive* zero-knowledge proofs (NISZK) [BFM88] and statistical randomized encoding with *one-sided privacy* (1RE) [AIK04, AIK15].

The NISZK model, introduced by Blum, Feldman and Micali [BFM88], restricts the prover to send a single message to the verifier at the expense of allowing the parties to share a common reference string that was pre-sampled by a trusted (efficient) dealer.<sup>2</sup> The notion of statistical randomized encoding with one-sided privacy was introduced by Applebaum, Ishai, and Kushile-vitz [AIK04] (under the term semi-private encoding) as a relaxation of REs in which the privacy condition should hold only for yes-instances.

We show that the corresponding complexity classes  $\mathcal{NISZK}^{PUB}$  and  $\mathcal{IRE}$  are essentially equivalent.

### **Theorem 1.1.** It holds that $\mathcal{NISZK}^{PUB} \subseteq 1\mathcal{RE}$ and, in the non-uniform setting, $1\mathcal{RE} \subseteq \mathcal{NISZK}^{PUB}$ .

The "non-uniform" setting refers to the case where all efficient entities (the client, the dealer, and the RE/SZK simulators) are modeled by polynomial-size circuits. The theorem shows that, non-uniformly, the class  $\mathcal{NISZK}^{PUB}$  is *equivalent* to the class  $\mathcal{IRE}$ . It is known that  $\mathcal{NISZK}^{PUB} \subseteq \mathcal{SZK}$  [PS05] and, by definition, we have that  $\mathcal{SRE} \subseteq \mathcal{IRE}$ . Hence, together with Theorem 1.1, we derive the following interesting picture (in the non-uniform setting):

$$\mathcal{SRE} \subseteq \mathcal{IRE} = \mathcal{NISZK}^{\text{PUB}} \subseteq \mathcal{SZK}.$$

Note that if SZK collapses to SRE then all intermediate classes also collapse. This means that the question of putting SZK inside SRE boils down to two separate questions: "Can statistical zero-knowledge be made non-interactive?" ( $NISZK^{PUB} = SZK$ ?) and "Can one-side privacy be upgraded to full privacy?" (SRE = 1RE?). Nicely, each of these well motivated questions is "pure"

<sup>&</sup>lt;sup>2</sup>Our description corresponds to the *public-parameter model*, which is widely used in the literature (see [PS05] and references therein). This setting generalizes the original *common random string* (crs) model proposed by Blum et al. [BFM88], in which the reference string is simply a uniformly random string of polynomial length. Following [CCKV08], we use the superscripts PUB and CRS to distinguish between these two variants. Observe that  $\mathcal{NISZK}^{CRS} \subseteq \mathcal{NISZK}^{PUB}$ .

in the sense that it only addresses one object (either randomized encoding or zero-knowledge proofs). We further mention that the first question ( $\mathcal{NISZK} = \mathcal{SZK}$ ?) is a well-known open problem that was studied before by [GSV99].<sup>3</sup>

### 1.1.2 Consequences of Randomized Encoding for Intractable Problems

Another way to compare SZK to SRE is by asking what are the consequences of the existence of computationally-intractable problems in the class. For example, the following theorem was proven by Ostrovsky.

#### **Theorem 1.2** ([Ost91]). If SZK is not in BPP, then Auxiliary-Input One-way functions exist.<sup>4</sup>

Auxiliary-input one-way functions (ai-OWF) are keyed functions that achieve a very weak form of one-wayness. Roughly speaking, for each adversary there exists a set of hard keys on which the adversary fails to invert the function. (See [Gol01] for definition.) However, it may be the case that there is no universal set of keys which is simultaneously hard for all efficient adversaries.

For SRE we prove (Section 6) the following stronger implication:

### **Theorem 1.3.** If SRE is not in BPP, then infinitely-often one-way functions exist.

Infinitely-often one-way functions (io-OWFs) are essentially standard one-way functions except that their hardness holds over a (universal) set of infinitely many input lengths. This notion is considered to be significantly stronger than ai-OWFs. For example, while it is possible to construct ai-OWFs based on the worst-case hardness of graph-isomorphism (GI), it is unknown how to obtain io-OWF from such an assumption. By Theorem 1.3, such a GI-based io-OWF would follow from the equivalence of SZK and SRE. More generally, a proof of such an equivalence would allow us to base io-OWFs on worst-case hardness in SZK improving the 25-year old classical result of [Ost91].

Theorem 1.3 also explains why all the candidates of Agrawal et al. [AIKP15] for computationallyhard problems in SRE imply the existence of one-way functions – Such an assumption is inherently necessary to separate SRE from BPP.

We can further ask what are the implications of an average-case hard problem in these complexity classes. Roughly speaking, a promise problem  $\Pi$  is average-case hard if it is equipped with a probability distribution D such that no efficient algorithm can classify correctly an instance xsampled from D with probability significantly better than 1/2. Ostrovsky's result can be used to prove that the existence of an average-case average-case hard language in SZK implies the existence of a one-way function. The following (stronger) theorem is implicit in the work of Ong and Vadhan [OV08].

**Theorem 1.4** (implicit in [OV08]). If there exists an average-case hard language in SZK then a constant-round statistically-hiding commitments (CRSC) exists.

<sup>&</sup>lt;sup>3</sup>More precisely, [GSV99] focused on the CRS model, and provided several necessary and sufficient conditions for the equality  $\mathcal{NISZK}^{CRS} = \mathcal{SZK}$ .

<sup>&</sup>lt;sup>4</sup>This theorem, and all the other results in this section, is formulated in the uniform setting. If one considers a non-uniform variant of SZK, then the theorem holds by changing BPP to P/poly and by relaxing the notion of AIOWFs to be computable by polynomial-size circuits. Similar modifications can be applied to the other theorems of this section.

As a general primitive, CRCS implies the existence of one-way functions, and is believed to be strictly stronger due to the black-box separation of [HHRS15]. We derive a stronger implication if we have randomized encoding for an average-case hard problem. Specifically, we consider the class  $\mathcal{PRE}$  of problems that admit *perfect randomized encoding* [AIK04] – a strong a variant of  $\mathcal{SRE}$ which achieves perfect correctness (zero-decoding error), perfect privacy (the simulators perfectly simulates the encoding) and enjoys some additional syntactic properties. (See Section 4 for a formal definition.)

**Theorem 1.5.** If there exists an average-case hard language in  $\mathcal{PRE}$  then collision-resistance hash functions (CRH) exist.

The proof of the theorem is sketched in Section 7. CRH imply CRSC but the converse is not known to be true. Hence, this implication is seemingly stronger than the one proven in [OV08]. Extending this theorem to the case of SRE is left as an interesting open problem.

## 2 Our Techniques

We explain the high-level idea behind the proof of Theorem 1.1. It is instructive to note that all the complexity classes SZK, NISZK, IRE and SRE essentially capture different variants of "statistical-distance" problems. Indeed, as we already saw, for a SRE-problem II, the membership of x boils down to determining whether the distribution Enc(x) is close to one of two distributions  $Sim_{YES}$  and  $Sim_{NO}$  which are statistically-far apart from each other. Notably, these distributions are *universal* and they depend only on the problem II (and not on the input x). The work of [SV03] also shows that, for any SZK-problem II, there exists an efficient mapping from an instance x to a pair distributions  $(A_x, B_x)$  which are statistically-close if x is a yes-instance and statisticallyfar otherwise. However, in contrast to the case of SREs, the distributions  $(A_x, B_x)$  are *instance dependent*. In particular, two different yes-instances x and x' may be mapped to completely different pairs of distributions  $(A_x, B_x)$  and  $(A_{x'}, B_{x'})$ .

In the intermediate notion of  $\mathcal{NISZK}$ , one of the distributions, say *B*, corresponds to the dealer's distribution and so it becomes universal [SCPY98, GSV99].<sup>5</sup> Correspondingly, all yesinstances *x* are mapped to this single universal distribution, i.e.,  $A_x \approx B$ . ( $A_x$  essentially corresponds to the simulated version of the public-parameter). For no-instances, the distribution  $A_x$ may be instance-dependent. Similarly, for  $1\mathcal{RE}$ , only yes-instances are mapped by Enc(x) to some universal yes-distribution  $Sim_{YES}$ , whereas the encoding of a no-instance Enc(x) may be instancedependent. Overall, the privacy properties of  $1\mathcal{RE}$  and the zero-knowledge properties of  $\mathcal{NISZK}$ match nicely. Still, there is one technical difference with respect to the requirements on the distributions of no-instances.

In  $1\mathcal{RE}$ , correctness requires the existence of a single decoder that distinguishes between the yes-distribution  $\operatorname{Sim}_{\operatorname{YES}}$  to all the no-distributions  $\{\operatorname{Enc}(x)\}_{x\in\Pi_{NO}}$ . This means that  $\operatorname{Sim}_{\operatorname{YES}}$  is "universally-far" from all the no-distributions. In contrast, the soundness property of  $\mathcal{NISZK}$  requires from every no-distribution  $A_x$  to be "disjoint" from B in the following sense: A random sample from the universal distribution  $b \stackrel{R}{\leftarrow} B$  should fall, with high probability, outside the support of  $A_x$ . To prove Theorem 1.1 we should be able to move from "universal-farmess" to "disjointness"

<sup>&</sup>lt;sup>5</sup>Interestingly, in the CRS model, this distribution is simply the uniform distribution and it is therefore also *problem-independent*.

and vice versa. While it is relatively straightforward to convert disjointness to universal-farness (e.g., via parallel-repetition), the converse direction requires some work.

As a concrete (and somewhat simplified) example, imagine the case where we have a single pair of distributions X and Y, where X outputs, with probability  $1 - \varepsilon$ , a random *n*-bit string whose first bit is 1, and, with probability  $\varepsilon$ , a random *n*-bit string whose first bit is 0. Assume that Y does exactly the opposite. These distributions are  $(1-2\varepsilon)$ -far in statistical distance, but they do not satisfy the disjointness property as their supports are equal. The key observation is to note that a typical  $y \stackrel{R}{\leftarrow} Y$  value, has much larger weight under Y compared to its weight under X. When these distributions are implemented by circuits that use m random bits as inputs, this means that the set of preimages  $Y^{-1}(y)$  is likely to be significantly larger than the set  $X^{-1}(y)$ . In other words, the entropy  $e_1$  of the conditional distribution [r|Y(r) = y] is larger than the entropy  $e_2$  of the conditional distribution [r|X(r) = y]. Following the approach of [GSV99], we can turn these distributions to be disjoint by hashing out about  $e_1 \ll e \ll e_2$  random bits from r, and appending the result h(r) to the output. That is, we define a pair of new distributions by X' = (X(r), h, h(r))and Y' = (Y(r), h, h(r)) where h is sampled from a 2-universal family of hash functions.<sup>6</sup> One can now show that for a typical  $y \stackrel{R}{\leftarrow} Y$  (and most h's), the conditional distribution [h(r)|Y(r) = y]is almost uniform, whereas the conditional distribution [h(r)|X(y) = y] has small support. This means that a random sample from Y' is likely to land out of the support of X', as required.

The actual construction introduces some additional technicalities. Most notably, it requires an estimation on the amount of entropy of the distribution which is sampled by  $Sim_{YES}$ , the simulator of the original encoding. We overcome this problem by treating this value as a non-uniform advice. We note that this advice is short (of logarithmic length) and so one may hope to simply try all possible values. The problem is that some of these values will violate the zero-knowledge property, while others would violate soundness. Unfortunately, we do not know how to "combine" together several faulty NISZK protocol into a single good protocol. The question of finding a way around this problem and achieving a fully uniform reduction is left for future research.

### 2.1 A Broader Perspective

We mainly view our results as indicating that SRE and SZK are unlikely to be equal. However, from a broader point of view, our results may be interpreted as saying that the two classes are actually close variants of each other. This is similar in spirit to a recent result (of the same authors) [AR16] that reveals a close connection between *private simultaneous message protocols* (PSM) [FKN94] and Zero-Information Arthur-Merlin (ZAM) protocols [GPW15]. PSMs and ZAMs can be viewed as the communication-complexity analog of Randomized Encodings and Zero-Knowledge proofs, where instead of limiting the computational power of the client, we split it into two non-communicating (computationally-unbounded) parties Alice and Bob each holding different parts of the input  $x = (x_A, x_B)$ . It is shown in [AR16] that the communication complexity of ZAM protocols is closely related to the randomness complexity of (variants of) PSMs, and vice versa. This is conceptually similar to some of the current results (e.g.,  $1RE = NISZK^{PUB}$ ) though the computational setting introduces different technical challenges, and correspondingly it requires a significantly different approach.

<sup>&</sup>lt;sup>6</sup>More generally, we could use any seeded randomness extractor that extracts e almost uniform bits from any  $e_2$ -bit source.

**Organization.** We begin with some standard preliminaries in Section 3. In Section 4 we provide formal definitions of statistical zero knowledge proofs, statistical randomized encoding and their variants. Theorem 1.1 is proved in Section 5, Theorem 1.3 in Section 6 and Theorem 1.5 in Section 7.

## **3** Preliminaries

**Basic Definitions.** For a finite set S, let  $s \stackrel{R}{\leftarrow} S$  denote an element that is sampled uniformly at random from S, and let U(S) denote the corresponding random variable. The uniform distribution over n-bit strings is denoted by  $U_n$ . The support of a random variable X is the set  $\supp(X) := \{x \mid \Pr[X = x] > 0\}$ . The Shannon entropy of X is  $H(X) := -\sum_{z} \Pr[X = z] \log \Pr[X = z]$ . For a distribution D, we let  $\otimes^k D$  be the probability distribution over k-tuples where each element is sampled independently according to D. Similarly, for a randomized algorithm F(x), we let  $\otimes^k F(x)$  be a k-tuple of k independent samples of F(x). We sometimes make the coins of a randomized algorithm F explicit by writing F(x; r) where  $r \stackrel{R}{\leftarrow} U_{s(x)}$  denotes the random coins used on an input x and s(x) denotes the randomness complexity of F on an input x, which, by default, is assumed to solely depend on the length of x.

Statistical Distance. The statistical distance between a pair of random variables X and Y distributed over the set Z is defined as

$$\Delta(X;Y) := \frac{1}{2} \sum_{z \in Z} |\Pr[X = z] - \Pr[Y = z]|.$$

Equivalently,  $\Delta(X;Y) = \max_A |\Pr[A(X) = 1] - \Pr[A(Y) = 1]|$  where the maximum ranges over all Boolean functions  $A: Z \to \{0,1\}$ . We write  $\Delta_{x_1 \notin D_1, \dots, x_k \notin D_k}(F(x_1, \dots, x_k); G(x_1, \dots, x_k))$ to denote the statistical distance between two random variables obtained as a result of sampling  $x_i$ 's from  $D_i$ 's and applying the functions F and G to  $(x_1, \dots, x_k)$ , respectively. We will use the following properties of statistical distance and entropy.

**Fact 3.1.** Let X and Y be a pair of random variables. Then the following holds:

- 1. [Vad99, Fact 3.2.2] For every (possibly randomized) function F, we have that  $\Delta(F(X); F(Y)) \leq \Delta(X; Y)$ .
- 2. [Vad99, Fact 3.3.9] Let D be the range of X and Y, then  $|H(X) H(Y)| \le (\log |D|) \cdot \Delta(X;Y) + 1.$
- 3. [Vad99, Lemma 3.1.15] For any integer q > 0, we have that  $1 2\exp(-q(\Delta(X;Y))^2/2) \le \Delta(\otimes^q X; \otimes^q Y) \le q \Delta(X;Y)$ .
- 4. [SV03, Fact 2.5] Suppose that  $X = (X_1, X_2)$  and  $Y = (Y_1, Y_2)$  are distributed over a set  $D \times E$  such that: (a)  $X_1$  and  $Y_1$  are identically distributed; and (b) with probability greater than  $1 \varepsilon$  over  $x \stackrel{R}{\leftarrow} X_1$ , we have  $\Delta(X_2|_{X_1=x}, Y_2|_{Y_1=x}) \leq \delta$ . Then  $\Delta(X, Y) \leq \varepsilon + \delta$ .
- 5. (cf. Appendix A.1) If  $\Delta(X;Y) \ge 1-\varepsilon$ , then, for any t > 1, it holds that  $\Pr_{x \leftarrow X}[\Pr[X = x] < t \cdot \Pr[Y = x]] \le \varepsilon t$ .

**Flattening.** We will use the following notion of  $\Delta$ -flat distributions from [GSV99].

**Definition 3.2** (Flat Distributions). Let X be a distribution. An element x of supp(X) is called  $\varepsilon$ -typical if  $|\log(1/\Pr[X = x]) - H(X)| \le \varepsilon$ . We say that X is  $\Delta$ -flat if for every t > 0 the probability that an element chosen from X is  $(t \cdot \Delta)$ -typical is at least  $1 - 2^{-t^2+1}$ .

A 0-flat distribution is uniform on its support, and is simply referred to as a *flat* distribution. A natural way to flatten a distribution is via parallel repetition.

**Lemma 3.3** (Flattening Lemma [Vad99, GSV99]). Let D be a distribution such that for all x from  $\operatorname{supp}(D)$  we have that  $D(x) \geq 2^{-m}$ . Then, for any  $k \in \mathbb{N}$ , the distribution  $\otimes^k D$  is  $(\sqrt{k} \cdot m)$ -flat.

**Hashing.** A family  $\mathcal{H}$  of functions mapping a domain  $\mathcal{D}$  to a range  $\mathcal{R}$  is 2-universal [CW79] if for every two elements  $x \neq y$  from  $\mathcal{D}$  and a, b from  $\mathcal{R}$  it holds that  $\Pr_{h \in \mathcal{H}}[h(x) = a \wedge h(y) = b] = \frac{1}{|\mathcal{R}|^2}$ . We write  $\mathcal{H}_{n,m}$  to denote a 2-universal family from  $\{0,1\}^n$  to  $\{0,1\}^m$ . There are efficient constructions of 2-universal families of hash functions  $\mathcal{H}_{n,m}$  that can be evaluated and sampled in poly(n,m) time [CW79].

**Lemma 3.4** (Leftover Hash Lemma [ILL89, GSV99]). Let  $\mathcal{H}$  be a 2-universal family of hash functions mapping a domain  $\mathcal{D}$  to a range  $\mathcal{R}$ . Let X be a flat distribution on  $\mathcal{D}$  such that for all  $x \in \operatorname{supp}(X)$  we have that  $\Pr[X = x] \leq \alpha/|\mathcal{R}|$ . Then

$$\Delta_{\substack{h \stackrel{R}{\leftarrow} \mathcal{H}}}((h, h(X)); (h, U(\mathcal{R}))) \le O(\alpha^{1/3}).$$

Sampling distributions via circuits. Let X be a circuit with m input and n output gates. We will sometimes abuse notation and use X to denote the random variable  $X(U_m)$  which corresponds to the output distribution of the circuit induced by "feeding" a uniformly chosen n-bit input. We let  $X^{-1}(x)$  denote the set of preimages of x under X, i.e.,  $X^{-1}(x) := \{r \in \{0,1\}^m \mid X(r) = x\}$ . Observe that  $\Pr[X = x] = 2^{-m} \cdot |X^{-1}(x)|$ .

## 4 $\mathcal{NISZK}$ and $\mathcal{SRE}$

A promise problem [ESY84]  $\Pi$  is a pair of two non-intersecting sets of strings ( $\Pi_{\text{YES}}, \Pi_{\text{NO}}$ ). The strings in  $\Pi_{\text{YES}}$  are called *yes-instances* and the strings in  $\Pi_{\text{NO}}$  are called *no-instances*. Let  $\chi_{\Pi}(x)$ be the characteristic function of  $\Pi$  which outputs 1 on yes-instances and 0 on no-instances. Note that a promise problem is a generalization of a language  $L \subseteq \{0, 1\}^*$ , i.e., L is translated into a promise problem  $\Pi_L$  where L corresponds to the set of yes-instances and  $\{0, 1\}^* \setminus L$  corresponds to the set of no-instances. (See [Gol06] for a survey.)

**Definition 4.1** (statistical randomized encoding [IK00, AIK04]). We say that an efficient randomized algorithm Enc is a  $\varepsilon$ -private and  $\delta$ -correct statistical randomized encoding of a promise problem  $\Pi = (\Pi_{\text{YES}}, \Pi_{\text{NO}})$  (abbreviated ( $\varepsilon$ ,  $\delta$ )-SRE), if the following holds:

 $\varepsilon$ -PRIVACY FOR YES-INSTANCES: There exists an efficient simulator  $\mathsf{Sim}_{YES}$  such that for every yesinstance  $x_{YES}$  of length n from  $\Pi$ ,  $\Delta(\mathsf{Sim}_{YES}(1^n); \mathsf{Enc}(x_{YES})) \leq \varepsilon(n)$ .

 $\varepsilon$ -PRIVACY FOR NO-INSTANCES: There exists an efficient simulator  $Sim_{NO}$ , such that for every noinstance  $x_{NO}$  of length n from  $\Pi$ ,  $\Delta(Sim_{NO}(1^n); Enc(x_{NO})) \leq \varepsilon(n)$ .  $\delta$ -CORRECTNESS: There exists a computationally-unbounded decoder Dec, such that for every instance  $x \in (\Pi_{\text{YES}} \cup \Pi_{\text{NO}})$  of length n,  $\Pr[\text{Dec}(\text{Enc}(x)) \neq \chi_{\Pi}(x)] \leq \delta(n)$ . By default,  $\varepsilon(n)$  and  $\delta(n)$  are required to be negligible functions.

**Perfect Encoding** [AIK04]. A randomized encoding which is 0-private (resp., 0-correct) is called *perfectly* private (resp., *perfectly correct*). For an input of length n, let s(n) denote the length of the random strings used by Enc and let t(n) be the output length of the encoding. A perfectly private and perfectly correct randomized encoding whose simulators use s(n) coins, their support satisfy  $supp(Sim_{YES}(1^n)) \cup supp(Sim_{NO}(1^n)) = \{0,1\}^{t(n)}$ , and 1 + s(n) = t(n) is called *perfect*. (See [AIK04] for an intuitive explanation of these requirements.)

**One-sided Encoding** [AIK04, AIK15]. A randomized encoding which is  $\varepsilon$ -private on yesinstances and  $\delta$ -correct is called *one-sided* (or *semi-private*) randomized encoding (denoted with  $(\varepsilon, \delta)$ -1RE)[AIK04, AIK15]. Clearly, any  $(\varepsilon, \delta)$ -SRE is also  $(\varepsilon, \delta)$ -1RE, though the converse does not necessarily hold. A *disjoint one-sided* randomized encoding is an encoding which is  $\varepsilon$ -private on yes-instances and, instead of standard correctness, it satisfies the following  $\rho$ -*disjointness* property: For every no-instance  $x_{NO}$  of length n from II, it holds that  $\Pr[Sim_{YES}(1^n) \in supp(Enc(x_{NO}))] \leq \rho(n)$ . We refer to such an encoding as  $(\varepsilon, \rho)$ -D1RE.

**Definition 4.2** (non-interactive statistical zero-knowledge [BSMP91]). A non-interactive statistical zero-knowledge proof system (NISZK) for a promise problem  $\Pi = (\Pi_{\text{YES}}, \Pi_{\text{NO}})$  is defined by probabilistic algorithms Prov (prover), Ver (verifier), Deal (dealer), and Sim (simulator), such that for every n-bit instance x the following holds

 $\alpha$ -COMPLETENESS: If  $x \in \Pi_{\text{YES}}$  then  $\Pr[\operatorname{Ver}(x, \sigma, \operatorname{Prov}(x, \sigma)) \neq 1] \leq \alpha(n)$ , where  $\sigma \xleftarrow{R} \operatorname{Deal}(1^n)$ .

 $\beta$ -SOUNDNESS: If  $x \in \Pi_{NO}$  then  $\Pr[\exists p : \operatorname{Ver}(x, \sigma, p) = 1] \leq \beta(n)$ , where  $\sigma \xleftarrow{R}{\leftarrow} \operatorname{Deal}(1^n)$ .

 $\gamma$ -ZERO-KNOWLEDGE: If  $x \in \Pi_{\text{YES}}$  then the pair  $(\sigma, p)$  is  $\gamma(n)$ -close in statistical distance to the pair  $(\sigma', p')$  where  $\sigma \stackrel{R}{\leftarrow} \text{Deal}(1^n), p \stackrel{R}{\leftarrow} \text{Prov}(x, \sigma)$  and  $(\sigma', p') \stackrel{R}{\leftarrow} \text{Sim}(x)$ .

The algorithms Ver, Deal, and Sim are required to be efficient, while the prover's algorithm Prov is allowed to be computationally unbounded. By default,  $\alpha$ ,  $\beta$  and  $\gamma$  are assumed to be negligible in n.

**Variants.** In the special case where the dealer  $\text{Deal}(1^n)$  samples  $\sigma$  uniformly from the set of all strings of length r(n) (for some polynomial  $r(\cdot)$ ), the proof system is called an interactive zero-knowledge proof system in the *common random string model* and is denoted by  $(\alpha, \beta, \gamma)$ -NISZK<sup>CRS</sup> [BFM88]. We will focus on the more general setting (defined above) where the dealer is allowed to use any arbitrary (polynomial-time samplable) distribution. This setting is referred to as the *public parameter model* and protocols in the model are denoted by  $(\alpha, \beta, \gamma)$ -NISZK<sup>PUB</sup>.<sup>7</sup>

**Remark 4.3** (Efficiency: Uniformity vs. Non-Uniformity). Randomized encodings and non-interactive statistical-zero knowledge proof systems can be defined either in the uniform setting where all efficient entities (encoder, RE-simulator, verifier, dealer, and NISZK-simulator) are assumed to be

<sup>&</sup>lt;sup>7</sup>The class NISZK<sup>PUB</sup> was implicitly considered in [BDLP88], and was later referred to as NISZK in the *auxiliary* string model [Dam00] and as protocol-dependent NISZK by [GB00]. Our terminology (NISZK in public parameter model) is taken from [PS05].

probabilistic polynomial-time algorithms, or in the non-uniform setting where these entities are represented by probabilistic polynomial-time algorithms which take a non-uniform advice. We will emphasize this distinction only when it matters (Theorem 5.1), and otherwise, (when the results are insensitive to the difference) ignore it.

**Definition 4.4** (Complexity classes). The complexity class SRE (resp., 1RE,  $NISZK^{PUB}$ ) is the set of all the promise problems that have an SRE (resp., 1RE, NISZK<sup>PUB</sup>).

## $5 \quad \mathcal{NISZK}^{\mathrm{pub}} = \mathcal{IRE}$

In this section we will prove Theorem 1.1. We start by showing that the notions of 1RE and D1RE are equivalent in Section 5.1. Then, based on this equivalence we prove that  $\mathcal{NISZK}^{PUB} = 1\mathcal{RE}$ . In the first part of the proof we show that  $\mathcal{NISZK}^{PUB} \subseteq 1\mathcal{RE}$  (cf. Section 5.2). In the second part of the proof we show that  $\mathcal{IRE} \subseteq \mathcal{NISZK}^{PUB}$  (cf. Section 5.3).

### 5.1 Equivalence of 1RE and D1RE

We start by showing how to convert a 1RE F for a promise problem  $\Pi$  into a D1RE G for the same problem. The construction is inspired by the techniques of [GSV99]. The encoding G consists of sufficiently many independent copies of F together with a hash of the randomness used to generate the copies. In order to achieve disjointness, while keeping privacy, the length of the hash is chosen such that for yes-instance the hash is close to uniform and in the case of no-instances the support of the hash output is relatively small.

We note that this construction is *non-uniform*. That is, the length of the hash is chosen using a non-uniform advice that depends on the entropy of the encoding distribution on yes-instances. It is an interesting open question whether one can give a uniform construction achieving disjointness.

**Theorem 5.1.** If the promise problem  $\Pi$  has a (possibly non-uniform) 1RE F, then it also has a non-uniform D1RE G. Moreover, if F is uniform then G can be implemented based on F and an advice of  $O(\log n)$  bits.

*Proof.* Let  $\Pi$  be a promise problem that has an  $\varepsilon$ -private and  $\delta$ -correct 1RE F, where  $\varepsilon$  and  $\delta$  are negligible. Let  $\mathsf{Sim}_F$  be the simulator showing the privacy of F on yes-instances. For an input length of n, let  $m = m(n) = \operatorname{poly}(n)$  denote the maximum bit-length of the randomness used by  $\mathsf{Sim}_F$  and F. We define a D1RE G(x) for  $\Pi$  as follows:

- 1. Parameters:  $q = 10^6 nm^2$ , m' = qm.
- 2. Non-uniform advice  $\ell := \lceil m' H(S_n) \sqrt{qn} \cdot m 2n \rceil$ .
- 3. Input:  $x \in \{0, 1\}^n$ .
- 4. Sample randomness  $r = (r_1, \ldots, r_q) \stackrel{R}{\leftarrow} \{0, 1\}^{m'}$  (where  $|r_i| = m$ ), and a pair-wise independent hash function  $h \stackrel{R}{\leftarrow} \mathcal{H}_{m'\ell}$ .
- 5. Output  $((F(x; r_1), \dots, F(x; r_q)), h, h(r)).$

To simplify notation, we let  $J_x(r) = (F(x, r_1), \ldots, F(x, r_q))$  and write  $J_x$  to denote the distribution induced by a uniform choice of  $r \stackrel{R}{\leftarrow} U_{m'}$ . We let  $S_n = \otimes^q \operatorname{Sim}_F(1^n)$ , and let  $\mathcal{H}$  denote the family  $\mathcal{H}_{m',\ell}$ .

We proceed with an analysis of the encoding G, starting with privacy. We define the simulator  $\operatorname{Sim}_G(1^n)$  to generate the random variable  $(S_n, U(\mathcal{H}), U_\ell)$ . Fix some yes-instance x of length n from  $\Pi$ . Our goal is to show that the statistical distance  $\varepsilon'(n)$  between  $\operatorname{Sim}_G(1^n)$  and G(x) is upper-bounded by some negligible function. First observe that, by the triangle inequality,  $\varepsilon'$  is upper-bounded by

$$\Delta(\mathsf{Sim}_G(1^n) ; (J_x, U(\mathcal{H}), U_\ell)) + \Delta((J_x, U(\mathcal{H}), U_\ell) ; G(x)).$$
(1)

By the  $\varepsilon$ -privacy of the original encoding and by Fact 3.1 item 3, the first summand satisfies

 $\Delta(\mathsf{Sim}_G(1^n); (J_x, U(\mathcal{H}), U_\ell)) = \Delta((S_n, U(\mathcal{H}), U_\ell); (J_x, U(\mathcal{H}), U_\ell)) \leq \Delta(S_n, J_x) \leq q\varepsilon(n) = \operatorname{neg}(n).$ It is left to analyze the second summand in (1), i.e., to upper-bound the quantity

$$\Delta_{\substack{R \\ \leftarrow \{0,1\}^{m'}, h \stackrel{R}{\leftarrow} \mathcal{H}}} ((J_x(r), h, U_\ell) \; ; \; (J_x(r), h, h(r))).$$

$$\tag{2}$$

Since the first entry is identically distributed in both distributions, it suffices to analyze the statistical distance between the two tuples conditioned on the outcome of the first entry  $J_x$ . Indeed, we prove the following claim.

**Claim 5.2.** With probability  $1 - 2^{-\Omega(n)}$  over  $z \stackrel{R}{\leftarrow} J_x$ , it holds that

r

$$\Delta_{\substack{r \leftarrow \{0,1\}^{m'}, h \leftarrow \mathcal{H}}} ([J_x(r), h, U_\ell | J_x(r) = z] ; [J_x(r), h, h(r) | J_x(r) = z]) < 2^{-\Omega(n)}.$$
(3)

It follows (by Fact 3.1 item 4) that (2) is upper-bounded by  $2^{-\Omega(n)}$ .

Proof of Claim 5.2. Recall that on any input x the encoding F uses at most m random bits, and so any element in its support has weight at least  $2^{-m}$ . Hence, due to the Flattening Lemma 3.3, the distribution  $J_x$  is  $\Delta$ -flat for  $\Delta = \sqrt{q}m$ . Since  $z \stackrel{R}{\leftarrow} J_x$  is  $(\sqrt{n}\Delta)$ -typical with probability at least  $1 - O(2^{-n})$ , it suffices to show that (3) holds for every  $(\sqrt{n}\Delta)$ -typical z.

Fix some  $(\sqrt{n\Delta})$ -typical z from  $J_x$  and consider the distribution  $(J_x(r), h, h(r))$  conditioned on  $J_x(r) = z$ . The conditional distribution of r is uniform over the set  $J_x^{-1}(z)$ . We will show below that

$$\log(|J_x^{-1}(z)|) \ge \ell + n \tag{4}$$

Therefore we can apply the Leftover Hash Lemma 3.4 to the distribution of  $r \stackrel{R}{\leftarrow} J_x^{-1}(z)$  with  $\mathcal{R} = \{0,1\}^{\ell}$  and  $\alpha = 2^{-n}$ , and conclude that the distribution of  $(J_x(r), h, h(r))$  conditioned on  $J_x(r) = z$  is  $O(2^{-n/3})$ -close to the distribution  $(z, U(\mathcal{H}), U_{\ell})$ .

It remains to prove (4). First, we show that the entropies  $H(J_x)$  and  $H(S_n)$  are close. Indeed, by the privacy of F, we have that  $\Delta(\text{Sim}_F(1^n); F(x)) \leq \varepsilon(n)$  and therefore (by Fact 3.1 item 3)  $\Delta(J_x; S_n) \leq q\varepsilon(n)$ . Hence, by Fact 3.1 item 2, we get that, for all sufficiently large n's,

$$|H(J_x) - H(S_n)| \le m' q \varepsilon(n) + 1 \le 2, \tag{5}$$

where the second inequality follows by noting that  $\varepsilon(n)$  is negligible in n, and m', q are polynomials in n. Now, recall that z is  $(\sqrt{n}\Delta)$ -typical, and therefore  $\log(|J_x^{-1}(z)|) \ge m' - H(J_x) - \sqrt{n}\Delta$ . Plugging in (5) we conclude that

$$\log(|J_x^{-1}(z)|) \ge m' - H(S_n) - 2 - \sqrt{n\Delta} \ge \underbrace{[m' - H(S_n) - \sqrt{n\Delta} - 2n]}_{=\ell} + (n-3) + n \ge \ell + n,$$

where the last inequality holds for  $n \geq 3$ .

We move on to prove the disjointness property. Fix some no-instance x. Our goal is to upperbound

$$\Pr\left[\mathsf{Sim}_G(1^n) \in \operatorname{supp}(G(x))\right] = \Pr\left[(S_n, U(\mathcal{H}), U_\ell) \in \operatorname{supp}(G(x))\right]$$
(6)

by some negligible function. For  $z \stackrel{R}{\leftarrow} S_n$ , let  $\mathcal{E} = \mathcal{E}(z)$  be the event that  $|J_x^{-1}(z)| \leq 2^{\ell-n}$ . By marginalizing the probability, we can upper-bound (6) by

$$\Pr_{z \stackrel{R}{\leftarrow} S_n, h \stackrel{R}{\leftarrow} \mathcal{H}, w \stackrel{R}{\leftarrow} \{0,1\}^{\ell}} [(z, h, w) \in \operatorname{supp}(G(x)) \mid \mathcal{E}(z)] + \Pr_{z \stackrel{R}{\leftarrow} S_n} [\neg \mathcal{E}(z)].$$

We will show that both the first and second summand are negligible in n.

Claim 5.3. 
$$\Pr_{z \leftarrow S_n, h \leftarrow \mathcal{H}, w \leftarrow \{0,1\}^{\ell}} [(z, h, w) \in \operatorname{supp}(G(x)) \mid \mathcal{E}(z)] \le 2^{-n}$$

*Proof.* By definition  $\operatorname{supp}(G(x)) = \{(J_x(r), h, h(r)) \mid r \in \{0, 1\}^{m'}, h \in \mathcal{H}\}$ . Therefore, for any fixed z and h the probability, over  $w \stackrel{R}{\leftarrow} \{0, 1\}^{\ell}$ , that the triple (z, h, w) lands in  $\operatorname{supp}(G(x))$  is exactly

$$\frac{|h(J_x^{-1}(z))|}{2^{\ell}} \le \frac{|J_x^{-1}(z)|}{2^{\ell}},$$

which is upper-bounded by  $2^{\ell-n}/2^{\ell} = 2^{-n}$  when we condition on  $\mathcal{E}(z)$ .

We conclude the proof by showing that for  $z \stackrel{R}{\leftarrow} S_n$  the event  $\mathcal{E}(z)$  happens almost surely. **Claim 5.4.**  $\Pr_{z \stackrel{R}{\leftarrow} S_n}[\log |J_x^{-1}(z)| \le \ell - n] \ge 1 - 2^{-\Omega(n)}.$ 

*Proof.* Call z good if

$$z ext{ is } (\sqrt{n\Delta}) ext{-typical}, ext{ where } \Delta = \sqrt{qm}, ext{(7)}$$

and

$$\Pr[S_n = z] \ge 2^{q/10} \Pr[J_x = z].$$
(8)

We begin by showing that, except with probability  $2^{-\Omega(n)}$ , a random  $z \stackrel{R}{\leftarrow} S_n$  is good. First, recall that  $\operatorname{Sim}_F(1^n)$  uses at most m random bits, and so any element in its support has weight at least  $2^{-m}$ . Hence, due to the Flattening Lemma 3.3, the distribution  $S_n$  is  $\Delta$ -flat for  $\Delta = \sqrt{q}m$  which implies that a random  $z \stackrel{R}{\leftarrow} S_n$  satisfies (7) with probability at least  $1 - 2^{-\Omega(n)}$ . Next, we show that, except with probability  $2^{-\Omega(n)}$ , a random  $z \stackrel{R}{\leftarrow} S_n$  satisfies (8). Indeed, due to the correctness property of F, we have that  $\Delta(\operatorname{Sim}_F(1^n); F(x)) \geq 1/2$  which implies (by Fact 3.1 item 3) that  $\Delta(S_n, J_x) \geq 1 - 2 \exp(-q/8)$ . Applying Fact 3.1 item 5, we conclude that

$$\Pr_{\substack{R \\ \leftarrow S_n}} [\Pr[S_n = z] < t \Pr[J_x = z]] \le t \cdot 2 \exp(-q/8),$$

for any  $t \ge 1$ . Taking  $t := 2^{q/10}$ , and noting that

2

$$t \cdot 2\exp(-q/8) \le 2t \cdot 2^{-q/8} = 2 \cdot 2^{q/10} \cdot 2^{-q/8} = 2^{-q/40+1} = 2^{-\Omega(n)},$$

г	-	-	٦	
L				
L				
-	_	_	۰	

we conclude that (8) holds for all but  $2^{-\Omega(n)}$ -fraction of the  $z \stackrel{R}{\leftarrow} S_n$ . It follows, by a union-bound, that, except with probability  $2^{-\Omega(n)}$ , a random  $z \stackrel{R}{\leftarrow} S_n$  is good.

Finally, we prove that for any good z it holds that  $\log |J_x^{-1}(z)| \leq \ell - n$ . By definition

$$|J_x^{-1}(z)| = 2^{m'} \cdot \Pr[J_x = z]$$

and by (8) the latter is upper-bounded by

$$2^{m'-q/10} \cdot \Pr[S_n = z].$$

Recalling that  $\Pr[S_n = z] \le 2^{-H(S_n) + \sqrt{n}\Delta}$  (since z is  $\sqrt{n}\Delta$ -typical) we conclude that

$$|J_x^{-1}(z)| \le 2^{m'-q/10-H(S_n)+\sqrt{n\Delta}}$$

Hence, we get that

$$\log |J_x^{-1}(z)| \le m' - H(S_n) + \sqrt{n\Delta} - q/10 \le \underbrace{\left[(m' - H(S_n) - \sqrt{n\Delta} - 2n)\right]}_{=\ell} - n + \underbrace{(3n + 3\sqrt{n\Delta} - q/10)}_{T}$$

Since  $q = 10^6 nm^2$  the expression T is always negative, and the claim follows.

This completes the proof of Theorem 5.1.

Now we show that if we repeat a D1RE polynomially many times we preserve the privacy of the encoding on yes-instances and gain the correctness security property of 1RE.

**Theorem 5.5.** Let  $\Pi$  be a promise problem that has an  $\varepsilon$ -private and  $\rho$ -disjoint D1RE F, where  $\varepsilon$  and  $\rho$  are negligible. Then, there exists G a 1RE for  $\Pi$  that is  $\varepsilon'$ -private and  $\delta$ -correct, where  $\varepsilon'$  and  $\delta$  are negligible.

*Proof.* For an instance x of length n, we define a randomized encoding G(x) to be  $\otimes^n F(x)$ . Since F is efficient, the encoding G is also efficient. We prove that G is a 1RE for  $\Pi$ .

PRIVACY FOR YES-INSTANCES: Let  $\operatorname{Sim}_F$  be the simulator showing the privacy of F on yes-instances. Define  $\operatorname{Sim}_G(1^n) := \otimes^n \operatorname{Sim}_F(1^n)$ . Take any yes-instance x from  $\Pi$ . We have that

$$\Delta(\mathsf{Sim}_G(1^n); G(x)) = \Delta(\otimes^n \mathsf{Sim}_F(1^n); \otimes^n F(x)) \le n \cdot \varepsilon(n)$$

where the last inequality holds due to Fact 3.1 item 3. Since  $\varepsilon(n)$  is negligible, we have that  $\varepsilon'(n) := n \cdot \varepsilon(n)$  is also negligible.

CORRECTNESS: Let  $Z = \bigcup_{x \in \Pi_{NO}} \operatorname{supp}(G(x))$ . The decoder Dec on input s outputs 0 if  $s \in Z$ ; and outputs 1, otherwise. Clearly, a no-instance is always decoded correctly. For a yes instance x, we upper-bound the decoding error by showing that  $\Pr[G(x) \in Z]$  is negligible. Since G is  $\varepsilon'$ -private on yes-instances, we have that

$$\Pr[G(x) \in Z] \le \Pr[\mathsf{Sim}_G(1^n) \in Z] + \varepsilon'(n).$$

By  $\rho$ -disjointness, it holds that  $\Pr[\operatorname{Sim}_F(1^n) \in \operatorname{supp}(F(x_{NO}))] \leq \rho(n)$ , for any no-instance  $x_{NO}$ . This implies that if we repeat this experiment n times we get that  $\Pr[\operatorname{Sim}_G(1^n) \in \operatorname{supp}(G(x_{NO}))] \leq \rho(n)^n$ . By a union bound, we conclude that  $\Pr[\operatorname{Sim}_G(1^n) \in Z] \leq 2^n \rho(n)^n$ , which implies that

$$\Pr[G(x) \in Z] \le 2^n \rho(n)^n + \varepsilon'(n) \le \operatorname{neg}(n).$$

The theorem follows.

## 5.2 From NISZK<sup>pub</sup> to 1RE

In this section we prove that  $\mathcal{NISZK}^{PUB} \subseteq 1\mathcal{RE}$ .

## **Theorem 5.6.** $\mathcal{NISZK}^{PUB} \subseteq 1\mathcal{RE}$ .

*Proof.* Let  $\Pi$  be a promise problem with  $(\alpha, \beta, \gamma)$ -NISZK<sup>PUB</sup> consisting of (Prov, Ver, Deal, Sim<sub>ZK</sub>), where  $\alpha, \beta, \gamma$  are negligible. By Theorem 5.5, it suffices to show that  $\Pi$  has a  $(\varepsilon, \rho)$ -D1RE Enc for some negligible  $\varepsilon$  and  $\rho$ . For an *n*-bit string *x*, we define a randomized encoding Enc(*x*) as follows:

Compute (σ, p) = Sim<sub>ZK</sub>(x).
 Compute the bit b = Ver(x, σ, p).
 If b = 1 output σ, otherwise output a fixed string z<sub>n</sub> ∉ supp(Deal(1<sup>n</sup>)).<sup>8</sup>

Observe that Enc is efficient because  $\text{Sim}_{ZK}$  and Ver are efficient. We prove that Enc is a D1RE. PRIVACY: We define  $\text{Sim}_{YES}(1^n) = \text{Deal}(1^n)$  and prove that for any yes instance x the distribution  $\text{Sim}_{YES}(1^n)$  is  $\varepsilon(n)$ -close to Enc(x) where  $\varepsilon(n) = \alpha(n) + 2 \cdot \gamma(n) = \text{neg}(n)$ . Fix some yes-instance x of length n. Due to the zero-knowledge property of NISZK, we have that

$$\Delta_{\sigma \xleftarrow{R} \mathsf{Deal}(1^n)} (\mathsf{Sim}_{\mathsf{ZK}}(x), (\sigma, \mathsf{Prov}(x, \sigma))) \le \gamma(n).$$

By the definition of the statistical distance, this implies that

$$\left| \Pr_{\sigma \xleftarrow{R} \mathsf{Deal}(n)} [\mathsf{Ver}(\sigma, x, \mathsf{Prov}(x, \sigma)) \neq 1] - \Pr_{(\sigma, p) \xleftarrow{R} \mathsf{Sim}_{\mathsf{ZK}}(x)} [\mathsf{Ver}(\sigma, x, p) \neq 1] \right| \leq \gamma(n).$$

1

Because of the correctness property of NISZK, we have that

$$\Pr_{\substack{\sigma \leftarrow \mathsf{Deal}(n)}} [\mathsf{Ver}(\sigma, x, \mathsf{Prov}(x, \sigma)) \neq 1] \leq \alpha(n).$$

This implies that

1

$$\Pr_{(\sigma,p) \stackrel{R}{\leftarrow} \mathsf{Sim}_{\mathsf{ZK}}(x)} [\mathsf{Ver}(\sigma, x, p) \neq 1] \le \alpha(n) + \gamma(n).$$

The latter inequality means that in the execution of Enc(x) the bit *b* equals to 1 except with the probability  $\alpha(n) + \gamma(n)$ . Hence,  $\Delta(Enc(x); Sim_{ZK}(x)[1]) \leq \alpha(n) + \gamma(n)$ , where  $Sim_{ZK}(x)[1]$  denotes the first component of the tuple output by the simulator. Because of the zero-knowledge property of NISZK and due to Fact 3.1 item 1, we have that  $\Delta(Sim_{ZK}(x)[1]; Deal(1^n)) \leq \gamma(n)$ . Finally, combining the last two inequalities, we get that

$$\Delta(\mathsf{Enc}(x);\mathsf{Deal}(1^n)) \le \alpha(n) + 2 \cdot \gamma(n) = \operatorname{neg}(n)$$

DISJOINTNESS: Let x be a no-instance of II. Let  $E \subseteq \text{supp}(\text{Deal}(1^n))$  denote the set of the strings admitting a proof for the no-instance x, i.e.,  $E := \{\sigma \in \text{supp}(\text{Deal}(1^n)) \mid \exists p : \text{Ver}(\sigma, x, p) = 1\}$ . By Enc's construction we have that  $\text{supp}(\text{Enc}(x)) \subseteq E \cup \{z_n\}$ . This implies that

$$\Pr[\mathsf{Deal}(1^n) \in \operatorname{supp}(\mathsf{Enc}(x))] \le \Pr[\mathsf{Deal}(1^n) \in E \cup \{z_n\}] \stackrel{(\star)}{=} \Pr[\mathsf{Deal}(1^n) \in E] \le \beta(n),$$

<sup>&</sup>lt;sup>8</sup>For example, such a z(n) can be efficiently constructed by appending a trailing 1 to the output of  $\mathsf{Deal}(1^n)$  and setting z(n) to the all-zero string.

where the last inequality follows from the soundness property of NISZK, and the equality (\*) holds because  $z_n \notin \text{supp}(\text{Deal}(1^n))$ .

### 5.3 From 1RE to $NISZK^{pub}$

**Theorem 5.7.** If the promise problem  $\Pi$  has a (possibly non-uniform) 1RE F, then it also has a non-uniform NISZK<sup>PUB</sup> proof system. Moreover, if F is uniform then the NISZK<sup>PUB</sup> proof system can be implemented based on F and an advice of  $O(\log n)$  bits.

*Proof.* Let  $\Pi \in I\mathcal{RE}$ . Due to Theorem 5.1, there exists a non-uniform  $(\varepsilon, \rho)$ -D1RE Enc for  $\Pi$  such that  $\varepsilon$  and  $\rho$  are negligible. Let s(n) denote the randomness complexity of the encoding Enc when it is applied to an *n*-bit input x, and let  $\operatorname{Sim}_{RE}$  be the simulator showing the privacy of Enc on yes-instances. We construct a proof system (Prov, Ver, Deal,  $\operatorname{Sim}_{ZK}$ ) for  $\Pi$  as follows:

- Deal: Given  $1^n$ , the dealer outputs  $Sim_{RE}(1^n)$ .
- Prov: Given an *n*-bit input x and a string  $\sigma$  from Deal, the prover samples a random  $r \in \{0,1\}^{s(n)}$  subject to  $\text{Enc}(x,r) = \sigma$ , and sends it to the verifier. If no such r exists the prover sends some arbitrary message.
- Ver: Given  $(x, \sigma, r)$ , the verifier accepts if  $Enc(x, r) = \sigma$ , and other rejects.
- $Sim_{ZK}$ : Given x, the simulator  $Sim_{ZK}$  samples a random r and outputs the pair (Enc(x, r), r).

We show that (Prov, Ver, Deal,  $Sim_{ZK}$ ) forms a NISZK for  $\Pi$ .

COMPLETENESS: Consider some yes-instance x of length n. Recall that, by the privacy of D1RE, the simulator's distribution  $Sim_{RE}(1^n)$  is  $\varepsilon(n)$ -close to Enc(x), which implies that

 $\Pr[\mathsf{Sim}_{\mathsf{RE}}(1^n) \in \operatorname{supp}(\mathsf{Enc}(x))] \ge 1 - \varepsilon(n).$ 

Hence, except with probability  $\varepsilon(n)$ , for a string  $\sigma$  generated by  $Sim_{RE}(1^n)$ , the prover Prov can find r, such that  $Enc(x, r) = \sigma$ .

SOUNDNESS: For all no-instances x of  $\Pi$ , we have that

$$\Pr_{\substack{\sigma \leftarrow \mathsf{Deal}(1^n)}}[\exists p: V(x, \sigma, p) = 1] = \Pr_{\substack{\sigma \leftarrow \mathsf{Sim}_{\mathsf{RE}}(1^n)}}[\sigma \in \operatorname{supp}(\mathsf{Enc}(x))] \le \delta(n),$$

where the last inequality follows from the disjointness property of Enc.

ZERO KNOWLEDGE: For all yes-instances x of  $\Pi$ , we have that

$$\begin{split} \Delta & (\operatorname{Sim}_{\operatorname{ZK}}(x) \; ; \; (\sigma, \operatorname{Prov}(x, \sigma))) = \Delta & (\operatorname{Enc}(x, r), r) \; ; \; (\sigma, \operatorname{Prov}(x, \sigma))) \\ \sigma \stackrel{R}{\leftarrow} \operatorname{Sim}_{\operatorname{RE}}(1^n), r \stackrel{R}{\leftarrow} \{0,1\}^{s(n)} & ((\operatorname{Enc}(x, r), \operatorname{Prov}(x, \operatorname{Enc}(x, r))) \; ; \; (\sigma, \operatorname{Prov}(x, \sigma))) \\ & = \Delta & (\operatorname{Enc}(x, r), \operatorname{Prov}(x, \operatorname{Enc}(x, r))) \; ; \; (\sigma, \operatorname{Prov}(x, \sigma))) \\ & \leq \Delta & (\operatorname{Enc}(x, r); \sigma) \leq \varepsilon(n), \end{split}$$

where the second equality follows by recalling that  $Prov(\sigma)$  samples a random r subject to  $Enc(x, r) = \sigma$  and so (Enc(x, r), r) is identically distributed to (Enc(x, r), Prov(x, Enc(x, r))), and the first inequality follows from Fact 3.1 item 1.

## 6 If SRE is non-trivial then one-way functions exist

In this section we prove Theorem 1.3:

### **Theorem 1.3.** If SRE is not in BPP, then infinitely-often one-way functions exist.

Proof. Assume that infinitely-often one-way functions do not exist. Impagliazzo and Luby [IL89] showed that in this case every efficiently computable function g(x) can be "distributionally-inverted" in the following sense: For every inverse polynomial  $\alpha(\cdot)$ , there exists an efficient adversary A such that, for random  $x \in \{0,1\}^n$ , the pair (x,g(x)) is  $\alpha(n)$ -close to the pair (A(g(x)),g(x)). In other words, for most x's, A finds an almost uniform preimage of g(x). We refer to  $\alpha$  as the *deviation* of the inverter and set it to 1/10.

We will show that such an inverter allows to put SRE in BPP. Let  $\Pi$  be a promise problem in SRE with  $\varepsilon$ -private  $\delta$ -correct statistical encoding Enc for some negligible  $\varepsilon$  and  $\delta$ . Let  $\operatorname{Sim}_{\operatorname{YES}}$ and  $\operatorname{Sim}_{\operatorname{NO}}$  be the simulators of the encoding and define  $\operatorname{Sim}(1^n, b)$  to be a "joint" simulator which takes a single bit  $b \in \{0, 1\}$  as an input and outputs a sample from  $\operatorname{Sim}_{\operatorname{YES}}(1^n)$  if b = 1 and from  $\operatorname{Sim}_{\operatorname{NO}}(1^n)$  if b = 0. We decide  $\Pi$  via the following BPP procedure B: Given a string  $x \in \{0, 1\}^n$ , sample an encoding  $y \stackrel{R}{\leftarrow} \operatorname{Enc}(x)$  and  $\alpha$ -distributionally invert the simulator Sim on the string y. Take the resulting preimage  $(1^n, b, r)$  (where r is the coins of the simulator) and output the bit b.<sup>9</sup> We analyze the success probability of deciding  $\Pi$  with this procedure.

**Claim 6.1.** The procedure B decides  $\Pi$  with error probability of at most  $1/6 + 5\delta + \varepsilon + \alpha$ .

Proof. Let us focus on the case where  $x \in \{0,1\}^n$  is a yes-instance (the other case is symmetric). First consider an "ideal" version B' of the algorithm B in which (1) the string y is sampled from  $\operatorname{Sim}_{\operatorname{YES}}(1^n)$  and (2) the distributional inversion algorithm is perfect and has zero deviation. Observe that the gap between the error probability of the real algorithm B to the error probability of the ideal algorithm B' is at most  $\varepsilon + \alpha$  (this is due to  $\varepsilon$ -privacy and to  $\alpha$ -deviation of the actual inverter). Hence, it suffices to show that the ideal version errs with probability of at most  $1/6 + 5\delta$ .

For a given encoding y, the ideal algorithm outputs the right answer b = 1 with probability  $\frac{p_1(y)}{p_0(y)+p_1(y)}$  where  $p_0(y)$  denotes the weight of y under  $\operatorname{Sim}_{NO}(1^n)$  and  $p_1(y)$  denotes the weight of y under  $\operatorname{Sim}_{YES}(1^n)$ . By the  $\delta$ -correctness of the encoding and by Fact 3.1 item 5 (instantiated with t = 5), it holds that, except with probability at most  $5\delta$  over  $y \notin \operatorname{Sim}_{YES}(1^n)$ , we have that  $p_1(y) \geq 5p_0(y)$ . It follows, by a union bound, that the ideal algorithm errs with probability of at most  $5\delta + 1/6$ , as required.

It remain to notices, that since  $\delta$  and  $\varepsilon$  are negligible and  $\alpha$  is an inverse polynomial, we have that  $\Pi$  can be decided with success probability at least 2/3.

## 7 If $\mathcal{PRE}$ is hard on the average then CRH exist

In this section we will study the consequences of the existence of an average-case hard problem  $\Pi \in \mathcal{PRE}$ .

<sup>&</sup>lt;sup>9</sup>We assume that the output of  $Sim(1^n, b)$  uniquely determines the input length n and so the inverter must output a triple with a "right" input length n. This is without loss of generality since we can always concatenate the input length  $1^n$  to the encoding and to the output of Sim.

**Definition 7.1.** We say that a promise problem  $\Pi = (\Pi_{\text{YES}}, \Pi_{\text{NO}})$  is hard on average if there exists an efficient sampler S that given  $1^n$  outputs an n-bit instance of  $\Pi$  such that for every non-uniform efficient algorithm A,

$$\left| \Pr_{\substack{x \stackrel{R}{\leftarrow} S(1^n)}} [A(x) = \chi_{\Pi}(x)] - 1/2 \right| < \operatorname{neg}(n).$$

We say that the problem has efficient Yes/No samplers if it is possible to efficiently sample from the conditional Yes distribution  $Y_n = [S(1^n)|S(1^n) \in \Pi_{YES}]$  and from the conditional No distribution  $N_n = [S(1^n)|S(1^n) \in \Pi_{NO}].$ 

A collection of *claw-free pseudo-permutations* (CFPP) [GMR88, Dam87, Rus95] is a set of pairs of efficiently computable functions  $f^0, f^1 : \{0,1\}^n \to \{0,1\}^n$  for which it is hard to find a pair (u, v)which forms a *claw*, i.e.,  $f^0(u) = f^1(v)$ , or a *collapse*, i.e.,  $f^b(u) = f^b(v)$  and  $u \neq v$ . Collections of claw-free *permutations* (CFPs) correspond to the special case where  $f_0$  and  $f_1$  are permutations and so collapses simply do not exist.

**Definition 7.2** (claw-free functions). A collection of pairs of functions consists of an infinite set of indices, denoted  $\overline{I}$ , finite sets  $D_i$  for each  $i \in \overline{I}$ , and two functions  $f_i^0$  and  $f_i^1$  mapping  $D_i$  to  $D_i$ , respectively. Such a collection is called a claw-free pseudo-permutations if there exist three probabilistic polynomial-time algorithms I, D, and F such that the following conditions hold:

EASY TO SAMPLE AND COMPUTE: The random variable  $I(1^n)$  is assigned values in the set  $I \cap \{0,1\}^{p(n)}$  for some polynomial  $p(\cdot)$ . For each  $i \in \overline{I}$ , the random variable D(i) is distributed uniformly over  $D_i$ . For each  $i \in \overline{I}$ ,  $b \in \{0,1\}$  and  $x \in D_i$ ,  $F(b,i,x) = f_i^b(x)$ .

HARD TO FORM CLAWS: A pair (x, y) satisfying  $f_i^0(x) = f_i^1(y)$  is called a claw for index *i*. Let  $C_i$  denote the set of claws for index *i*. It is required that for every probabilistic polynomial-time algorithm A,

$$\Pr_{\substack{i \in I(1^n)}} [A(i) \in C_i] < \operatorname{neg}(n).$$

HARD TO FORM COLLAPSES: A pair (x, y) satisfying  $f_i^b(x) = f_i^b(y)$  is called a collapse for an index i and a bit b. Let  $T_{i,b}$  denote the set of collapses for (i, b). It is required that for every probabilistic polynomial-time algorithm A and every  $b \in \{0, 1\}$ ,

$$\Pr_{\substack{i \stackrel{\mathcal{R}}{\leftarrow} I(1^n)}} [A(i) \in T_{i,b}] < \operatorname{neg}(n).$$

If the last item holds for unbounded adversaries, i.e.,  $f_i^0$  and  $f_i^1$  are permutations over  $D_i$ , then the collection is called a collection of claw-free permutations.

It is known that CFPP's imply Collision-Resistant Hash functions (CRH) [Rus95]. We will show that the existence of an average-case hard problem  $\Pi \in \mathcal{PRE}$  implies the existence of CFPPs. We begin with the simpler case in which  $\Pi$  has an *efficient Yes/No samplers* and show that, in this case, we obtain a collection of claw-free permutations.

**Theorem 7.3.** If there exists an average-case hard language in  $\mathcal{PRE}$  with efficient Yes/No samplers then CFPs exist.

We will need the following simple claim.

**Claim 7.4.** Let  $\Pi$  be a promise problem with perfect randomized encoding g whose simulators are  $\operatorname{Sim}_{\operatorname{YES}}$  and  $\operatorname{Sim}_{\operatorname{NO}}$ . Define the functions  $h_x^0, h_y^1$  which are indexed by a pair of instances (x, y) of  $\Pi$  as follows:

$$h_x^0(r,b) = \begin{cases} g(x;r), & \text{if } b = 0, \\ \mathsf{Sim}_{NO}(r), & \text{otherwise;} \end{cases} \quad and \quad h_y^1(r,b) = \begin{cases} g(y;r), & \text{if } b = 0, \\ \mathsf{Sim}_{YES}(r), & \text{otherwise;} \end{cases}$$
(9)

Then the following holds for any n-bit strings x and y:

1. If  $x \in \Pi_{\text{YES}}$ , then  $h_y^0$  is a permutation. 2. If  $y \in \Pi_{\text{NO}}$ , then  $h_y^1$  is a permutation. 3. If  $(x, y) \in \Pi_{\text{NO}} \times \Pi_{\text{YES}}$  then  $\text{Im}(h_x^0) \cap \text{Im}(h_y^1) = \emptyset$ .

Proof. Let  $R_0$  and  $R_1$  denote  $\operatorname{Im}(\operatorname{Sim}_{NO})$  and  $\operatorname{Im}(\operatorname{Sim}_{YES})$ , respectively. Let s(n) denote the randomness complexity of g and let t(n) denote the output length of g. Since g is a perfect randomized encoding, we have that  $R_0 \cap R_1 = \emptyset$ ,  $R_0 \cup R_1 = \{0, 1\}^{t(n)}$ , and t(n) = s(n) + 1. Consider the case where  $x \in \Pi_{YES}$ . Then  $h_x^0(\cdot, 0) : \{0, 1\}^{s(n)} \to R_1$  is a bijection and  $h_x^0(\cdot, 1) : \{0, 1\}^{s(n)} \to R_0$ . Since  $R_0 \cap R_1 = \emptyset$ , the function  $h_x^0(\cdot, \cdot)$  is a permutation on  $R_0 \cup R_1 = \{0, 1\}^{t(n)}$ . Similarly, if  $y \in \Pi_{NO}$ , the function  $h_y^1(\cdot, \cdot)$  is a permutation on  $\{0, 1\}^{t(n)}$ .

In order to prove the third item, we observe that if  $x \in \Pi_{\text{NO}}$ , then  $\text{Im}(h_x^0) = R_0$ ; and if  $y \in \Pi_{\text{YES}}$ , then  $\text{Im}(h_y^1) = R_1$ . This implies that for all  $(x, y) \in \Pi_{\text{NO}} \times \Pi_{\text{YES}}$  it holds that  $\text{Im}(h_x^0) \cap \text{Im}(h_y^1) = R_0 \cap R_1 = \emptyset$ .

We can now prove Theorem 7.3.

Proof of Theorem 7.3. Let  $\Pi$  be an average-case hard language with efficient Yes/No samplers  $(Y_n, N_n)$ , and let g be a perfect randomized encoding for  $\Pi$ . For a pair of inputs (x, y) from  $\Pi$ , we say that (x, y) is a (YES, NO)-instance (resp., (NO, YES)), if x is a yes-instance and y is a no-instance (resp., if x is a no-instance and y is a yes-instance).

We construct a CFP family which is indexed by pairs  $(x, y) \in \Pi_{\text{YES}} \times \Pi_{\text{NO}}$ . Given a security parameter  $1^n$ , an index (x, y) is chosen by sampling  $x \stackrel{R}{\leftarrow} Y_n$  and  $y \stackrel{R}{\leftarrow} N_n$ . For each index (x, y) we let  $f_{(x,y)}^0 \equiv h_x^0$  and  $f_{(x,y)}^1 \equiv h_y^1$ , where  $h_x^0$  and  $h_x^1$  are defined as in (9). Recall that the domain and range of  $f_{x,y}^b$  are  $\{0,1\}^{t(n)}$  where t(n) is the output length of g's output. Clearly this collection is efficiently samplable and efficiently computable. Moreover, since our sampler always samples a (YES, NO)instance (x, y), it holds, due to Claim 7.4, that  $f_{(x,y)}^0 \equiv h_x^0$  and  $f_{(x,y)}^1 \equiv h_y^1$  are permutations on  $\{0,1\}^{t(n)}$ . We complete the proof by showing that claws are hard to find.

Recall that we assume that the distribution ensemble  $\{Y_n\}$  is computationally indistinguishable from  $\{N_n\}$ . By a standard hybrid argument, it follows that the pair  $(Y_n, N_n)$  is computationally indistinguishable from the pair  $(Y_n, Y_n)$  which, in turn, is computationally indistinguishable from the pair  $(N_n, Y_n)$ . Now assume, for the sake of contradiction, that there exists an efficient algorithm A that given  $(x, y) \stackrel{R}{\leftarrow} (Y_n, N_n)$  can find claws with non-negligible probability  $\varepsilon$ . We can use A to distinguish  $(Y_n, N_n)$  from  $(N_n, Y_n)$  as follows: Given (x, y) call A(x, y) and output 1 if A's output (u, v) forms a collision under  $h_x^0$  and  $h_y^1$ . By assumption, the resulting distinguisher outputs 1 when  $(x, y) \stackrel{R}{\leftarrow} (Y_n, N_n)$  with probability  $\varepsilon$ . In contrast, when  $(x, y) \stackrel{R}{\leftarrow} (N_n, Y_n)$ , the distinguisher never finds a claw since claws do not exist (due to Claim 7.4). Hence the distinguisher has a noticeable advantage of  $\varepsilon$ , in contradiction to our assumption. We continue by considering the more general case where  $\Pi$  is hard on average but does not admit efficient Yes/No samplers, and obtain, in this case, claw-free *pseudo-permutations* (whose existence still implies collision-resistance hash functions).

**Theorem 7.5.** If there exists an average-case hard language in  $\mathcal{PRE}$  then claw-free pseudopermutations (CFPP) exist.

Proof. The construction is identical to the one presented in Theorem 7.3, except that the index  $(x, y) \in \Pi \times \Pi$  is chosen by sampling both x and y independently from the distribution  $S(1^n)$  over which  $\Pi$  is average-case hard. By definition, the collection  $f_{(x,y)}^b = h_x^b$ , where h is defined as in (9), is efficiently samplable and efficiently computable. We verify that it is CFPP.

We begin by showing that  $f_{(x,y)}^0 = h_x^0$  is a pseudo-permutation (the case of  $f_{(x,y)}^1$  is analogous). Assume for the sake of contradiction that there is an algorithm A that can find collapses for  $f_{(x,y)}^0$  with a non-negligible probability  $\varepsilon$ . Using A we construct a new algorithm A' that has a non-negligible advantage in guessing  $\chi_{\Pi}(x)$  for  $x \stackrel{R}{\leftarrow} S(1^n)$ . Given an input  $x \stackrel{R}{\leftarrow} S(1^n)$ , the algorithm A' samples  $y \leftarrow S(1^n)$ , and then invokes A(x,y) to find a collapse (u,v) for  $f_{(x,y)}^0 = h_x^0$ . If A finds a valid collapse (i.e.,  $u \neq v$  and  $h_x^0(u) = h_x^0(v)$ ), the algorithm A' classifies the input x as a no-instance and outputs 0; otherwise A' outputs a random bit. Recall that when x is a yes-instance the function  $h_x^0$  is a permutation, and so it does not have collapses. Hence, A' outputs a correct answer whenever A finds a collapse. Also, when a collapse is not found, the success probability of A' is 1/2. Hence, the overall success probability of A' is

$$\Pr_{\substack{x \stackrel{R}{\leftarrow} S(1^n)}} [A'(x) = \chi_{\Pi}(x)] = 1/2 \cdot (1-\varepsilon) + 1 \cdot \varepsilon = 1/2 + \varepsilon/2,$$

in contradiction to the average-case hardness of  $\Pi$ .

We move on to show that it is hard to find claws. Assume for the sake of contradiction that there exists an efficient algorithm A that finds claws with a non-negligible probability  $\varepsilon$ . We construct a new algorithm A' that has a non-negligible advantage in guessing  $\chi_{\Pi}(x)$  for  $x \stackrel{R}{\leftarrow} S(1^n)$ . Let

$$p = \Pr_{\substack{x \stackrel{R}{\leftarrow} S(1^n), y \stackrel{R}{\leftarrow} S(1^n)}} [A(x, y) \text{ finds a claw } | x \in \Pi_{\text{NO}}].$$

We distinguish between two cases based on the value of p.

First, consider the case where  $p \ge \varepsilon/2$ . Then, by an averaging argument, there exists some fixed no-instance  $x_0$  for which

$$\Pr_{y}[A(x_0, y) \text{ finds a claw }] \ge \varepsilon/2.$$

Recall that when the index is a (NO, YES) pair there are no claws and so when A finds a claw, y must be a no-instance We can therefore construct a non-uniform algorithm that decides  $y \stackrel{R}{\leftarrow} S(1^n)$  as follows: Call  $A(x_0, y)$  and output zero ("no") if a collision is found and otherwise toss a random coin. The success probability is at least  $\varepsilon/2 + (1 - \varepsilon/2)/2 = 1/2 + \varepsilon/4$ .

Second, consider the case where  $p < \varepsilon/2$ . In this case, we determine whether  $x \stackrel{R}{\leftarrow} S(1^n)$  is a yes-instance or a no-instance via the following procedure A'. Sample  $y \stackrel{R}{\leftarrow} S(1^n)$ , and call A(x, y)

if A returns a valid claw, outputs 1 (classify x as a yes instance); otherwise, output a random bit. The success probability of A' can be marginalized as follows:

$$\begin{split} \Pr_{x}[A'(x) \text{ succeeds }] &= \Pr_{x,y}[A'(x) \text{ succeeds } |A(x,y) \text{ finds a claw }] \cdot \varepsilon \\ &+ \Pr_{x,y}[A'(x) \text{ succeeds } |A(x,y) \text{ doesn't find a claw }] \cdot (1-\varepsilon) \\ &= \Pr_{x}[x \in \Pi_{\text{YES}}|A(x,y) \text{ finds a claw }] \cdot \varepsilon + (1-\varepsilon)/2, \end{split}$$

Therefore, it suffices to show that

$$\Pr_{x}[x \in \Pi_{\text{YES}}|A(x,y) \text{ finds a claw }] \ge 2/3$$
(10)

since this implies that A' succeeds with probability of at least  $2/3 \cdot \varepsilon + (1 - \varepsilon)/2 = 1/2 + \varepsilon/6$ . To prove (10), we upper-bound by 1/3 the probability of the complementary event:

$$\Pr_{x}[x \in \Pi_{\text{NO}}|A(x,y) \text{ finds a claw}] = \frac{\Pr_{x,y}[A(x,y) \text{ finds a claw}|x \in \Pi_{\text{NO}}] \cdot \Pr_{x}[x \in \Pi_{\text{NO}}]}{\Pr[A(x,y) \text{ finds a claw }]} \le \frac{(\varepsilon/2) \cdot (2/3)}{\varepsilon} = \frac{1}{3},$$

where the inequality follows by our assumption  $(p < \varepsilon/2)$  and by the fact that  $\Pr_x[x \in \Pi_{NO}] < 2/3$ (since otherwise the trivial adversary that always outputs 0 breaks the average-case hardness of  $\Pi$ over  $S(1^n)$ ). The proof follows.

## A Omitted Proofs

### A.1 Proof of Item 5 of Fact 3.1

We prove that if  $\Delta(X; Y) \ge 1 - \varepsilon$ , then, for any t > 1, it holds that  $\Pr_{x \leftarrow X}[\Pr[X = x] < t \cdot \Pr[Y = x]] \le \varepsilon t$ .

*Proof.* We start by proving an additional claim:

Claim A.1. For any two distributions X, Y and a subset S of their domain, it holds that:

$$\Delta(X;Y) \le 1 - \sum_{x \in S} \min(\Pr[X=x], \Pr[Y=x]).$$

Proof.

$$\begin{split} 2\,\Delta(X;Y) &= \sum_{x} |\Pr[X=x] - \Pr[Y=x]| \\ &= \sum_{x \not\in S} |\Pr[X=x] - \Pr[Y=x]| + \sum_{x \in S} |\Pr[X=x] - \Pr[Y=x]| \\ &\leq \sum_{x \not\in S} \Pr[X=x] + \sum_{x \not\in S} \Pr[Y=x] + \sum_{x \in S} |\Pr[X=x] - \Pr[Y=x] \\ &= \sum_{x} \Pr[X=x] + \sum_{x} \Pr[Y=x] - \sum_{x \in S} (\Pr[X=x] + \Pr[Y=y] - |\Pr[X=x] - \Pr[Y=x]|) \\ &= 2 - 2 \sum_{x \in S} \min(\Pr[X=x], \Pr[Y=x]). \end{split}$$

The last equality holds because  $\sum_{x} \Pr[X = x] = 1 = \sum_{x} \Pr[Y = x]$ , and for all a, b we have that  $a + b - |a - b| = 2\min(a, b)$ .

Now we proceed to the proof of the lemma. Let  $S := \{x \mid \Pr[X = x] < t \cdot \Pr[Y = x]\}$ . Due to the claim, we have that

$$\Delta(X;Y) \le 1 - \sum_{x \in S} \min(\Pr[X=x], \Pr[Y=x])$$
(11)

We now give a lower bound for each summand  $\min(\Pr[X = x], \Pr[Y = x])$ . Namely, we show that

$$\forall x \in S \ \min(\Pr[X=x], \Pr[Y=x]) \ge \Pr[X=x]/t.$$
(12)

By the construction of S, we have that for any  $x \in S$   $\Pr[Y = x] > \Pr[X = x]/t$ . Hence, min $(\Pr[X = x], \Pr[Y = x]) \ge \min(\Pr[X = x], \Pr[X = x]/t)$ . Since t > 1, we have that min $(\Pr[X = x], \Pr[X = x]/t) = \Pr[X = x]/t$ . Combining inequalities 11 and REeq:part, we get that

$$\Delta(X;Y) \le 1 - \sum_{x \in S} \min(\Pr[X=x], \Pr[Y=x]) \le 1 - \sum_{x \in S} \Pr[X=x]/t = 1 - \Pr[X \in S]/t$$

Recall that by assumption  $1 - \varepsilon \leq \Delta(X; Y)$ , and therefore, we conclude that  $\varepsilon \geq \Pr[X \in S]/t$  implying that  $\Pr[X \in S] \leq \varepsilon t$ .
