Multi-Collision Resistant Hash Functions and their Applications

Itay Berman* Akshay Degwekar* Ron D. Rothblum†
Prashant Nalini Vasudevan*

September 26, 2017

Abstract

Collision resistant hash functions are functions that shrink their input, but for which it is computationally infeasible to find a collision, namely two strings that hash to the same value (although collisions are abundant).

In this work we study multi-collision resistant hash functions (MCRH) a natural relaxation of collision resistant hash functions in which it is difficult to find a $t$-way collision (i.e., $t$ strings that hash to the same value) although finding $(t-1)$-way collisions could be easy. We show the following:

- The existence of MCRH follows from the average case hardness of a variant of the Entropy Approximation problem. The goal in the entropy approximation problem (Goldreich, Sahai and Vadhan, CRYPTO ’99) is to distinguish circuits whose output distribution has high entropy from those having low entropy.
- MCRH imply the existence of constant-round statistically hiding (and computationally binding) commitment schemes. As a corollary, using a result of Haitner et al. (SICOMP, 2015), we obtain a blackbox separation of MCRH from any one-way permutation.

1 Introduction

Hash functions are efficiently computable functions that shrink their input and mimic ‘random functions’ in various aspects. They are prevalent in cryptography: both in theory and in practice. A central goal in the study of the foundations of cryptography has been to distill the precise, and minimal, security requirements necessary from hash functions for different applications.

One widely studied notion of hashing is that of collision resistant hash functions (CRH). Namely, hash functions for which it is computationally infeasible to find two strings that hash to the same value, even when such collisions are abundant. CRH have been extremely fruitful and have notable applications in cryptography such as digital signatures\(^1\) [GMR88], efficient argument systems for NP [Kil92, Mic00] and (constant-round) statistically hiding commitment schemes [NY89, DPP93, HM96].

In this work we study a natural relaxation of collision resistance. Specifically, we consider hash functions for which it is infeasible to find a \(t\)-way collision: i.e., \(t\) strings that all have the same hash value. Here \(t\) is a parameter, where the standard notion of collision resistance corresponds to the special case of \(t = 2\). Loosely speaking, we refer to such functions as multi-collision resistant hash functions (MCRH) and emphasize that, for \(t > 2\), it is a weaker requirement than that of standard collision resistance. To the best of our knowledge, MCRH were first considered by Joux [Jou04], who showed that for specific classes of hash functions called iterated hash functions, finding a large number of collisions is no harder than finding just two colliding inputs. We emphasize that Joux’s result only applies to iterated hash functions and in the general case (i.e., arbitrary hash functions) it seems that MCRH is a weaker property than CRH.

As in the case of CRH, to obtain a meaningful definition, we must consider keyed functions (since for non-keyed functions there are trivial non-uniform attacks). Thus, we define MCRH as follows (here and throughout this work, we use \(n\) to denote the security parameter.)

Definition 1.1 ((\(s,t\))-MCRH). Let \(s = s(n) \in \mathbb{N}\) and \(t = t(n) \in \mathbb{N}\) be functions computable in time \(\text{poly}(n)\). An \((s,t)\)-Multi-Collision Resistant Hash Function Family \((s,t)\)-MCRH consists of a probabilistic polynomial-time algorithm \(\text{Gen}\) that on input \(1^n\) outputs a circuit \(h\) such that:

- **\(s\)-Shrinkage:** The circuit \(h : \{0,1\}^n \rightarrow \{0,1\}^{n-s}\) maps inputs of length \(n\) to outputs of length \(n - s\).

- **\(t\)-Collision Resistance:** For every polynomial size family of circuits \(A = (A_n)_{n \in \mathbb{N}}\),

\[
\Pr_{(x_1,x_2,...,x_t)\leftarrow A_n(h), h\leftarrow \text{Gen}(1^n),} \left[ \begin{array}{c}
\text{For all } i \neq j, \\
\text{ } \text{ } \text{ } \text{ } h(x_i) = h(x_j) \text{ and } x_i \neq x_j
\end{array} \right] < \text{negl}(n).
\]

Note that the standard notion of CRH simply corresponds to \((1,2)\)-MCRH (which is easily shown to be equivalent to \((s,2)\)-CRH for any \(s = n - \omega(\log n)\)). We also remark that Definition 1.1 gives a non-uniform security guarantee, which is natural, especially in the context of collision resistance. Note though that all of our results are obtained by uniform reductions.

Remark 1.2 (Shrinkage vs. Collision Resistance). Observe that \((s,t)\)-MCRH are meaningful only when \(s \geq \log t\), as otherwise \(t\)-way collisions might not even exist (e.g., consider a function mapping

\(^1\)We remark that the weaker notion of universal one-way hash functions (UOWHF) (which is known to be implied by standard one-way functions) suffices for this application [NY89, Rom90].
inputs of length \( n \) to outputs of length \( n - \log(t - 1) \) in which each range element has exactly \( t - 1 \) preimages).

Moreover, we note that in contrast to standard CRH, it is unclear whether the shrinkage factor \( s \) can be trivially improved (e.g., by composition) while preserving the value of \( t \). Specifically, constructions such as Tree Hashing (aka Merkle Tree) inherently rely on the fact that it is computationally infeasible to find any collision. It is possible to get some trade-offs between the number of collisions and shrinkage. For example, given an \((s = 2, t = 4)\)-MCRH, we can compose it with itself to get an \((s = 4, t = 10)\)-MCRH. But it is not a priori clear whether there exist transformations that increase the shrinkage \( s \) while not increasing \( t \). We remark that a partial affirmative answer to this question was recently given in an independent and concurrent work by Bitansky et al. \( [BPK] \), as long as the hash function is substantially shrinking (see additional details in Section 1.2).

Thus, we include both the parameters \( s \) and \( t \) in the definition of MCRH, whereas in standard CRH the parameter \( t \) is fixed to 2, and the parameter \( s \) can be given implicitly (since the shrinkage can be trivially improved by composition).

**Remark 1.3** (Scaling of Shrinkage vs. Collisions). The shrinkage \( s \) is measured in bits, whereas the number of collisions \( t \) is just a number. A different definitional choice could have been to put \( s \) and \( t \) on the same “scale” (e.g., measure the logarithm of the number of collisions) so to make them more easily comparable. However, we refrain from doing so since we find the current (different) scaling of \( s \) and \( t \) to be more natural.

### 1.1 Our Results

The focus of this work is providing a systematic study of MCRH. We consider both the question of constructing MCRH and what applications can we derive from them.

#### 1.1.1 Constructions of MCRH

Since any CRH is in particular also an MCRH, candidate constructions are abundant (based on a variety of concrete computational assumptions). The actual question that we ask, which has a more foundational flavor, is whether we can construct MCRH from assumptions that are not known to imply CRH.

Our first main result is that the existence of MCRH follows from the average-case hardness of a variant of the Entropy Approximation problem studied by Goldreich, Sahai and Vadhan \( [GSV99] \). **Entropy Approximation**, denoted \( \text{EA} \), is a promise problem, where YES inputs are circuits whose output distribution (i.e., the distribution obtained by feeding random inputs to the circuit) has entropy at least \( k \), whereas NO inputs are circuits whose output distribution has entropy at most \( k - 1 \) (where \( k \) is a parameter that is unimportant for the current discussion). Here by entropy we specifically refer to Shannon entropy.\(^2\) Goldreich et al. showed that \( \text{EA} \) is complete for the class of (promise) problems that have non-interactive statistical zero-knowledge proofs (NISZK).

In this work we consider a variant of \( \text{EA} \), first studied by Dvir et al. \( [DGRV11] \), that uses different notions of entropy. Specifically, consider the promise problem \( \text{EA}_{\min, \max} \), where the goal now is to distinguish between circuits whose output distribution has \( \min \)-entropy\(^3\) at least \( k \) from

---

\(^2\)Recall that the Shannon Entropy of a random variable \( X \) is defined as \( H_{\text{Shannon}}(X) = E_{x \sim X} \left[ \log \left( \frac{1}{\Pr[x = x]} \right) \right] \).

\(^3\)For a random variable \( X \), the \( \min \)-entropy is defined as \( H_{\min}(X) = \min_{x \in \text{Supp}(X)} \log \left( \frac{1}{\Pr[x = x]} \right) \) whereas the \( \max \)-entropy is \( H_{\max}(X) = \log (|\text{Supp}(X)|) \).
those with \textit{max}-entropy at most \( k - 1 \). It is easy to verify that \( \text{EA}_{\min,\max} \) is an easier problem than \( \text{EA} \).

\textbf{Theorem 1} (Informal, see Theorem 3.6). \textit{If} \( \text{EA}_{\min,\max} \) \textit{is average-case hard, then there exist} \((s, t)\)-\( \text{MCRH} \), \textit{where} \( s = \sqrt{n} \) \textit{and} \( t = 6n^2 \).

(Note that in the \( \text{MCRH} \) that we construct there exist \( 2\sqrt{n} \)-way collisions, but it is computationally hard to find even a \( 6n^2 \)-way collision.)

In contrast to the original entropy approximation problem, we do not know whether \( \text{EA}_{\min,\max} \) is complete for \text{NISZK}. Thus, establishing the existence of \text{MCRH} based solely on the average-case hardness of \text{NISZK} (or \text{SZK}) remains open. Indeed such a result could potentially be an interesting extension of Ostrovsky’s [Ost91] proof that average-case hardness of \text{SZK} implies the existence of one-way functions.

\textbf{Instantiations.} Dvir et al. [DGRV11], showed that the average-case hardness of \( \text{EA}_{\min,\max} \) is implied by either the quadratic residuocity (\text{QR}) or decisional Diffie Hellman (\text{DDH}) assumptions.\footnote{In fact, [DGRV11] show that the same conclusion holds even if we restrict the problem to constant-depth (i.e., \text{NC}_0) circuits.}

It is not too hard to see that above extends to any encryption scheme (or even commitment scheme) in which ciphertexts can be perfectly re-randomized.\footnote{Given such a scheme consider a circuit that has, hard-coded inside, a pair of ciphertexts \((c_0, c_1)\) which are either encryptions of the same bit or of different bits. The circuit gets as input a bit \( b \) and random string \( r \) and outputs a re-randomization of \( c_b \) (using randomness \( r \)). If the scheme is perfectly re-randomizing (and perfectly correct) then the min-entropy of the output distribution in case the plaintexts disagree is larger than the max-entropy in case the plaintexts agree.}

The hardness of \( \text{EA}_{\min,\max} \) can also be shown to follow from the \textit{average-case} hardness of the Shortest Vector Problem or the Closest Vector Problem with approximation factor roughly \( \sqrt{n} \).\footnote{The hard distribution for \text{SVP}_{\sqrt{n}} \text{ and } \text{CVP}_{\sqrt{n}} \text{ is the first message from the 2-message honest-verifier } \text{SZK} \text{ proof system of Goldreich and Goldwasser [GG98]. In the case of } \text{CVP}_{\sqrt{n}}, \text{ the input is } (B, t, d) \text{ where } B \text{ is the basis of the lattice, } t \text{ is a target vector and } d \text{ specifies the bound on the distance of } t \text{ from the lattice. The distribution is obtained by sampling a random error vector } \eta \text{ from the ball of radius } d\sqrt{n}/2 \text{ centered at the origin and outputting } b \cdot t + \eta \text{ mod } \mathcal{P}(B), \text{ where } b \leftarrow \{0, 1\} \text{ and } \mathcal{P}(B) \text{ is the fundamental parallelopiped of } B. \text{ When } t \text{ is far from the lattice, this distribution is injective and hence has high min-entropy while when } t \text{ is close to the lattice, the distribution is not injective and hence has lower max-entropy. Similarly for } \text{SVP}_{\sqrt{n}}, \text{ on input } (B, a), \text{ the output is } \eta \text{ mod } \mathcal{P}(B) \text{ where } \eta \text{ is again sampled from a ball of radius } d\sqrt{n}/2.}

To the best of our knowledge the existence of \( \text{MCRH} \) based solely on the average-case hardness of \text{NISZK} (or \text{SZK}) remains open. Indeed such a result could potentially be an interesting extension of Ostrovsky’s [Ost91] proof that average-case hardness of \text{SZK} implies the existence of one-way functions.

Lastly, we remark that a similar argument establishes the hardness of \( \text{EA}_{\min,\max} \) based on the plausible assumption that graph isomorphism is average-case hard.\footnote{Note that the graph isomorphism is known to be solvable in polynomial-time for many natural distributions, and the recent breakthrough result of Babai [WM16] gives a quasi-polynomial worst-case algorithm. Nevertheless, it is still plausible that Graph Isomorphism is average-case quasi-polynomially hard (for some efficiently samplable distribution).}

\subsection{1.1.2 Applications of MCRH}

The main application that we derive from \text{MCRH} is a \textit{constant-round} statistically-hiding commitment scheme.

\textbf{Theorem 2} (Informally stated, see Theorem 4.4). \textit{Assume that there exists a} \((\log(t), t)\)-\text{MCRH}. \textit{Then, there exists a} 3-round \textit{statistically-hiding and computationally-binding commitment scheme}.  

\begin{itemize}
  \item \text{Instantiations.} Dvir et al. [DGRV11], showed that the average-case hardness of \( \text{EA}_{\min,\max} \) is implied by either the quadratic residuocity (\text{QR}) or decisional Diffie Hellman (\text{DDH}) assumptions.\footnote{In fact, [DGRV11] show that the same conclusion holds even if we restrict the problem to constant-depth (i.e., \text{NC}_0) circuits.}
  \item It is not too hard to see that above extends to any encryption scheme (or even commitment scheme) in which ciphertexts can be perfectly re-randomized.\footnote{Given such a scheme consider a circuit that has, hard-coded inside, a pair of ciphertexts \((c_0, c_1)\) which are either encryptions of the same bit or of different bits. The circuit gets as input a bit \( b \) and random string \( r \) and outputs a re-randomization of \( c_b \) (using randomness \( r \)). If the scheme is perfectly re-randomizing (and perfectly correct) then the min-entropy of the output distribution in case the plaintexts disagree is larger than the max-entropy in case the plaintexts agree.}
  \item The hardness of \( \text{EA}_{\min,\max} \) can also be shown to follow from the \textit{average-case} hardness of the Shortest Vector Problem or the Closest Vector Problem with approximation factor roughly \( \sqrt{n} \).\footnote{The hard distribution for \text{SVP}_{\sqrt{n}} \text{ and } \text{CVP}_{\sqrt{n}} \text{ is the first message from the 2-message honest-verifier } \text{SZK} \text{ proof system of Goldreich and Goldwasser [GG98]. In the case of } \text{CVP}_{\sqrt{n}}, \text{ the input is } (B, t, d) \text{ where } B \text{ is the basis of the lattice, } t \text{ is a target vector and } d \text{ specifies the bound on the distance of } t \text{ from the lattice. The distribution is obtained by sampling a random error vector } \eta \text{ from the ball of radius } d\sqrt{n}/2 \text{ centered at the origin and outputting } b \cdot t + \eta \text{ mod } \mathcal{P}(B), \text{ where } b \leftarrow \{0, 1\} \text{ and } \mathcal{P}(B) \text{ is the fundamental parallelopiped of } B. \text{ When } t \text{ is far from the lattice, this distribution is injective and hence has high min-entropy while when } t \text{ is close to the lattice, the distribution is not injective and hence has lower max-entropy. Similarly for } \text{SVP}_{\sqrt{n}}, \text{ on input } (B, a), \text{ the output is } \eta \text{ mod } \mathcal{P}(B) \text{ where } \eta \text{ is again sampled from a ball of radius } d\sqrt{n}/2.}
  \item To the best of our knowledge the existence of \( \text{MCRH} \) based solely on the average-case hardness of \text{NISZK} (or \text{SZK}) remains open. Indeed such a result could potentially be an interesting extension of Ostrovsky’s [Ost91] proof that average-case hardness of \text{SZK} implies the existence of one-way functions.
  \item Lastly, we remark that a similar argument establishes the hardness of \( \text{EA}_{\min,\max} \) based on the plausible assumption that graph isomorphism is average-case hard.\footnote{Note that the graph isomorphism is known to be solvable in polynomial-time for many natural distributions, and the recent breakthrough result of Babai [WM16] gives a quasi-polynomial worst-case algorithm. Nevertheless, it is still plausible that Graph Isomorphism is average-case quasi-polynomially hard (for some efficiently samplable distribution).}
\end{itemize}
We note that Theorem 2 is optimal in the sense of holding for MCRH that are minimally shrinking. Indeed, as noted in Remark 1.2, \((s,t)\)-MCRH with \(s \leq \log(t - 1)\) exist trivially and unconditionally.

It is also worthwhile to point out that by a result of Haitner et al. \[HNO + 09\], statistically-hiding commitment schemes can be based on the existence of any one-way function. However, the commitment scheme of \[HNO + 09\] uses a polynomial number of rounds of interaction and the main point in Theorem 2 is that we obtain such a commitment scheme with only a constant number of rounds.

Moreover, by a result of \[HHRS15\], any fully black-box construction of a statistically hiding commitment scheme from one-way functions (or even one-way permutations) must use a polynomial number of rounds. Loosely speaking, a construction is “fully black-box” \[RTV04\] if (1) the construction only requires an input-output access to the underlying primitive and (2) the security proof also relies on the adversary in a black-box way. Most constructions in cryptography are fully black-box. Since our proof of Theorem 2 is via a fully black-box construction, we obtain the following immediate corollary:

**Corollary 3** (Informally stated, see Theorem 5.3). There is no fully blackbox construction of MCRH from one-way permutations.

Corollary 3 can be viewed as an extension of Simon’s \[Sim98\] blackbox separation of CRH from one-way permutations.

### 1.2 Related Works

**Generic Constructions of CRH.** Peikert and Waters \[PW11\] construct CRH from lossy trapdoor functions. Their construction can be viewed as a construction of CRH from \(EA_{\min,\max}\) with a huge gap. (Specifically, the lossy trapdoor function \(h\) is either injective (i.e., \(H_{\min}(h) \geq n\)) or very shrinking (i.e., \(H_{\max}(h) < 0.5n\)).\(^8\) One possible approach to constructing CRH from lossy functions with small ‘lossiness’ \((H_{\max}(h) / H_{\min}(h))\) is to first amplify the lossiness and then apply the \[PW11\] construction. Pietrzak et al. \[PRS12\] rule out this approach by showing that it is impossible to improve the ‘lossiness’ in a black-box way.\(^9\) We show that even with distributions where the gap is tiny, we can achieve weaker yet very meaningful notions of collision-resistance.

Applebaum and Raykov \[AR16\] construct CRH from any average-case hard language with a **Perfect Randomized Encoding** in which the encoding algorithm is one-to-one as a function of the randomness. Perfect Randomized Encodings are a way to encode the computation of a function \(f\) on input \(x\) such that information-theoretically, the only information revealed about \(x\) is the value \(f(x)\). The class of languages with such randomized encodings \(PRE\) is contained in \(PZK\). Their assumption of an average-case hard language with a perfect randomized encoding implies \(EA_{\min,\max}\) as well.

**Constant-Round Statistically Hiding Commitments from SZK Hardness.** The work of Ong and Vadhan \[OV08\] yields constant-round statistically-hiding commitment schemes from

---

\(^8\)The trapdoor to the lossy function is not used in the construction of CRH.

\(^9\)In contrast, it is easy to see that repetition amplifies the *additive* gap between the min-entropy and the max-entropy. In fact, we use this in our construction.
average-case hardness of $\text{SZK}$.$^{10}$ Our construction of statistically-hiding commitments via $\text{MCRH}$ is arguably simpler, although it relies on a stronger assumption ($\text{EA}_{\min,\max}$) instead of average-case hardness of $\text{SZK}$.

**Distributional CRH.** A different weakening of collision resistance was considered by Dubrov and Ishai [DI06]. Their notion, called “distributional collision-resistant” in which it may be feasible to find some specific collision, but it is hard to sample a random collision pair. That is, given the hash function $h$, no efficient algorithm can sample a pair $(z_1, z_2)$ such that $z_1$ is uniform and $z_2$ is uniform in the set $\{z : h(z) = h(z_1)\}$. The notions of $\text{MCRH}$ and distributional $\text{CRH}$ are incomparable and whether one can be constructed from the other is open.

**Min-Max Entropy Approximation.** The main result of the work of Dvir et al. [DGRV11] (that was mentioned above) was showing that the problem $\text{EA}$ for degree-3 polynomial mappings (i.e., where the entropies are measured by Shannon entropy) is complete for $\text{SZK}_L$, a sub-class of $\text{SZK}$ in which the verifier and the simulator run in logarithmic space. They also construct algorithms to approximate different notions of entropy in certain restricted settings (but their algorithms do not violate the assumption that $\text{EA}_{\min,\max}$ is average-case hard).

**1.2.1 Independent Works**

$\text{MCRH}$ have been recently considered in an independent work by Komargodski et al. [KNY17] (which was posted online roughly four months prior to the first public posting of our work). Komargodski et al. study the problem, arising from Ramsey theory, of finding either a clique or an independent set (of roughly logarithmic size) in a graph, when such objects are guaranteed to exist. As one of their results, [KNY17] relate a variant of the foregoing Ramsey problem (for bipartite graphs) to the existence of $\text{MCRH}$. We emphasize that the focus of [KNY17] is in studying computational problems arising from Ramsey theory, rather than $\text{MCRH}$ directly.

Beyond the work of [KNY17], there are two other concurrent works that specifically study $\text{MCRH}$ [KNY, BPK] (and were posted online simultaneously to our work). The main result of [KNY] (whose authors are the same as [KNY17]) is that the existence of $\text{MCRH}$ (with suitable parameters) implies the existence of efficient argument-systems for $\text{NP}$, à la Kilian’s protocol [Kil92]. Komargodski et al. [KNY] also prove that $\text{MCRH}$ imply constant-round statistically hiding commitments (similarly to Theorem 2), although their result only holds for $\text{MCRH}$ who shrink their input by a constant multiplicative factor. Lastly, [KNY] also show a blackbox separation between $\text{MCRH}$ in which it is hard to find $t$ collisions from those in which it is hard to find $t+1$ collisions.

Bitansky et al. [BPK] also study $\text{MCRH}$, with the motivation of constructing efficient argument-systems. They consider both a keyed version of $\text{MCRH}$ (as in our work) and an unkeyed version (in which, loosely speaking, the requirement is that adversary cannot produce more collisions than those it can store as non-uniform advice). [BPK] show a so-called “domain extension” result for $\text{MCRH}$ that are sufficiently shrinking. Using this result they construct various succinct and/or zero-knowledge argument-systems, with optimal or close-to-optimal round complexity. In particular, they show the existence of 4 round zero-knowledge arguments for $\text{NP}$ based on $\text{MCRH}$, and, assuming unkeyed $\text{MCRH}$, they obtain a similar result but with only 3 rounds of interaction.

---

$^{10}$Actually, Ong and Vadhan [OV08] only construct instance-dependent commitments. Dvir et al. [DGRV11] attribute the construction of constant-round statistically hiding commitments from average-case hardness of $\text{SZK}$ to a combination of [OV08] and an unpublished manuscript of Guy Rothblum and Vadhan [RV09].
1.3 Our Techniques

We provide a detailed overview of our two main results: Constructing MCRH from $EA_{\min, \max}$ and constructing constant-round statistically-hiding commitment scheme from MCRH.

1.3.1 Constructing MCRH from $EA_{\min, \max}$

Assume that we are given a distribution on circuits $\{C: \{0,1\}^n \rightarrow \{0,1\}^{2n}\}$ such that it is hard to distinguish between the cases $H_{\min}(C) \geq k$ or $H_{\max}(C) \leq k - 1$, where we overload notation and let $C$ also denote the output distribution of the circuit when given uniformly random inputs. Note that we have set the output length of the circuit to $2n$ but this is mainly for concreteness (and to emphasize that the circuit need not be shrinking).

Our goal is to construct an MCRH using $C$. We will present our construction in steps, where in the first case we start off by assuming a very large entropy gap. Specifically, for the first (over-simplified) case, we assume that it is hard to distinguish between min-entropy $\geq n$ vs. max-entropy $\leq n/2$. Note that having min-entropy $n$ means that $C$ is injective.

Warmup: The case of $H_{\min}(C) \geq n$ vs. $H_{\max}(C) \ll n/2$. In this case, it is already difficult to find even a 2-way collision in $C$: if $H_{\min}(C) \geq n$, then $C$ is injective and no collisions exist. Thus, if one can find a collision, it must be the case that $H_{\max}(C) \leq n/2$ and so any collision finder distinguishes the two cases.

The problem though is that $C$ by itself is not shrinking, and thus is not an MCRH. To resolve this issue, a natural idea that comes to mind is to hash the output of $C$, using a pairwise independent hash function. Thus, the first idea is to choose $f: \{0,1\}^{2n} \rightarrow \{0,1\}^{n-s}$, for some $s \geq 1$, from a family of pairwise independent hash functions and consider the hash function $h(x) = f(C(x))$.

If $H_{\min}(C) \geq n$ (i.e., $C$ is injective), then every collision in $h$ is a collision on the hash function $f$. On the other hand, if $H_{\max}(C) \leq n/2$, then $C$ itself has many collisions. To be able to distinguish between the two cases, we would like that in the latter case there will be no collisions that originate from $f$. The image size of $C$, if $H_{\max}(C) \ll n/2$, is smaller than $2^{n/2}$. If we set $s$ to be sufficiently small (say constant) than the range of $f$ has size roughly $2^n$. Thus, we are hashing a set into a range that is more than quadratic in its size. In such case, we are “below the birthday paradox regime” and a random function on this set will be injective. A similar statement can be easily shown also for functions that are merely pairwise independent (rather than being entirely random).

Thus, in case $C$ is injective, all the collisions appear in the second part of the hash function (i.e., the application of $f$). On the other hand, if $C$ has max-entropy smaller than $n/2$, then all the collisions happen in the first part of the hash function (i.e., in $C$). Thus, any adversary that finds a collision distinguishes between the two cases and we actually obtain a full-fledged CRH (rather than merely an MCRH) at the cost of making a much stronger assumption.

The next case that we consider is still restricted to circuits that are injective (i.e., have min entropy $n$) in one case but assumes that it is hard to distinguish injective circuits from circuits having max-entropy $n - \sqrt{n}$ (rather than $n/2$ that we already handled).

\footnotesize
11 This setting (and construction) is similar to that of Peikert and Waters's construction of CRH from lossy functions [PW11].

12 Recall that a collection of functions $F$ is $k$-wise independent if for every distinct $x_1, \ldots, x_k$, the distribution of $(f(x_1), \ldots, f(x_k))$ (over the choice of $f \leftarrow F$) is uniform.
The case of $H_{\text{min}}(C) \geq n$ vs. $H_{\text{max}}(C) \leq n - \sqrt{n}$. The problem that we encounter now is that in the low max entropy case, the output of $C$ has max-entropy $n - \sqrt{n}$. To apply the above birthday paradox argument we would need the range of $f$ to be of size roughly $(2^n - \sqrt{n})^2 \gg 2^n$ and so our hash function would not be shrinking. Note that if the range of $f$ were smaller, than even if $f$ were chosen entirely at random (let alone from a pairwise independent family) we would see collisions in this case (again, by the birthday paradox).

The key observation that we make at this point is that although we will see collisions, there will not be too many of them. Specifically, suppose we set $s = \sqrt{n}$. Then, we are now hashing a set of size $2^n - \sqrt{n}$ into a range of size $2^n - \sqrt{n}$. If we were to choose $f$ entirely at random, this process would correspond to throwing $N = 2^n - \sqrt{n}$ balls (i.e., the elements in the range of $C$) into $N$ bins (i.e., elements in the range of $f$). It is well-known that in such case, with high probability, the maximal load for any bin will be at most $\frac{\log(N)}{\log \log(N)} < n$. Thus, we are guaranteed that there will be at most $n$ collisions.

Unfortunately, the work of Alon et al. [ADM+99] shows that the same argument does not apply to functions that are merely pairwise independent (rather than entirely random). Thankfully though, suitable derandomizations are known. Specifically, it is not too difficult to show that if we take $f$ from a family of $n$-wise independent hash functions, then the maximal load will also be at most $n$ (see Section 2.2 for details).\footnote{We remark that more efficient constructions are known, see Remark 2.4.}

Similarly to before, in case $C$ is injective, there are no collisions in the first part. On the other hand, in case $C$ has max-entropy at most $n - \sqrt{n}$, we have just argued that there will be less than $n$ collisions in the second part. Thus, an adversary that finds an $n$-way collision distinguishes between the two cases and we have obtained an $(s,t)$-MCRH, with $s = \sqrt{n}$ and $t = n$ (i.e., collisions of size $2\sqrt{n}$ exist but finding a collision of size even $n$ is computationally infeasible).

The case of $H_{\text{min}}(C) \geq k$ vs. $H_{\text{max}}(C) \leq k - \sqrt{n}$. We want to remove the assumption that when the min-entropy of $C$ is high, then it is in fact injective. Specifically, we consider the case that either $C$’s min-entropy is at least $k$ (for some parameter $k \leq n$) or its max entropy is at most $k - \sqrt{n}$. Note that in the high min-entropy case, $C$ — although not injective — maps at most $2^{n-k}$ inputs to every output (this is essentially the definition of min-entropy). Our approach is to apply hashing a second time (in a different way), to effectively make $C$ injective, and then apply the construction from the previous case.

Consider the mapping $h'(x) = (C(x), f(x))$, where $f$ will be defined ahead. For $h'$ to be injective, $f$ must be injective over all sets of size $2^{n-k}$. Taking $f$ to be pairwise-independent will force to set its output length to be too large, in a way that will ruin the entropy gap between the cases.

As in the previous case, we resolve this difficulty by using many-wise independent hashing. Let $f : \{0,1\}^n \rightarrow \{0,1\}^{n-k}$ be a $3n$-wise independent hash function. If $H_{\text{min}}(C) \geq k$, then the same load-balancing property of $f$ that we used in the previous case, along with a union bound, implies that with high probability (over the choice of $f$) there will be no $3n$-way collisions in $h'$. Our final construction applies the previous construction on $h'$. Namely,

$$h_{C,f,g}(x) = g(C(x), f(x)),$$

for $f : \{0,1\}^n \rightarrow \{0,1\}^{n-k}$ and $g : \{0,1\}^{3n-k} \rightarrow \{0,1\}^{n-\sqrt{n}}$ being $3n$-wise and $2n$-wise independent hash functions, respectively. We can now show that
The case of $H_{\text{min}}(C) \geq k$ vs. $H_{\text{max}}(C) \leq k - 1$. This case is handled by reduction to the previous case. The main observation is that if $C$ has min-entropy at least $k$, and we take $\ell$ copies of $C$, then we get a new circuit with min-entropy at least $\ell \cdot k$. In contrast, if $C$ had max-entropy at most $k - 1$, then $C'$ has max-entropy at most $\ell \cdot k - \ell$. Setting $\ell = k$, we obtain that in the second case the max-entropy is $n' - \sqrt{n'}$, where $n' = \ell \cdot k$ is the new input length. Thus, we have obtained a reduction to the $\sqrt{n'}$ gap case that we already handled.

1.3.2 Constructing Constant-Round Statistically-Hiding Commitment from MCRH

The fact that MCRH imply constant-round statistically-hiding commitments can be shown in two ways. The first, more direct way, uses only elementary notions such as $k$-wise independent hashing and is similar to the interactive hashing protocol of Ding et al. [DHRS07]. An alternative method, is to first show that MCRH imply the existence of an $(O(1))-block$ inaccessible entropy generator [HRVVW09, HV17]. The latter was shown by [HRVVW09, HV17] to imply the existence of constant-round statistically-hiding commitments. We discuss these two methods next and remark that in our actual proof we follow the direct route.

1.3.2.1 Direct Analysis

In a nutshell our approach is to follow the construction of Damgård et al. [DPP93] of statistically-hiding commitments from CRH, while replacing the use of pairwise independent hashing, with the interactive hashing protocol of Ding et al. [DHRS07]. We proceed to the technical overview, which does not assume familiarity with any of these results.

**Warmup: Commitment from (Standard) CRH.** Given a family of collision-resistant hash functions $\mathcal{H} = \{h: \{0,1\}^n \rightarrow \{0,1\}^{n-1}\}$, a natural first attempt is to have the receiver sample the hash function $h \leftarrow \mathcal{H}$ and send it to the sender. The sender, trying to commit to a bit $b$, chooses $x \leftarrow \{0,1\}^n$ and $r \leftarrow \{0,1\}^n$, and sends $(y = h(x), r, \sigma = \langle r, x \rangle \oplus b)$ to the receiver.
commitment is defined as \( c = (h, y, r, \sigma) \). To reveal, the sender sends \((x, b)\) to the receiver, which verifies that \( h(x) = y \) and \( \sigma = \langle r, x \rangle \oplus b \). Pictorially, the commit stage is as follows:

\[
\begin{array}{ccc}
5(b) & \rightarrow & \text{R} \\
 & \downarrow^{h} & \\
x, r & \leftarrow & \{0,1\}^n \quad c = (h(x), r, \langle r, x \rangle \oplus b) \\
\end{array}
\]

The fact that the scheme is computationally binding follows immediately from the collision resistance of \( h \): if the sender can find \((x, 0)\) and \((x', 1)\) that pass the receiver’s verification, then \( x \neq x' \) and \( h(x) = h(x') \).

Arguing that the scheme is statistically-hiding is trickier. The reason is that \( h(x) \) might reveal a lot of information on \( x \). What helps us is that \( h \) is shrinking, and thus some information about \( x \) is hidden from the receiver. In particular, this means that \( x \) has positive min-entropy given \( h(x) \). At this point we would like to apply the Leftover Hash Lemma (LHL) to show that for any \( b \), the statistical distance between \((h(x), r, \langle r, x \rangle \oplus b)\) and \((h(x), r, u)\) is small. Unfortunately, the min-entropy level is insufficient to derive anything meaningful from the LHL and indeed the distance between these two distributions is a constant (rather than negligible as required).

To reduce the statistical distance, we increase the min-entropy via repetition. We modify the protocol so that the sender selects \( k \) values \( x = (x_1, \ldots, x_k) \leftarrow \{0,1\}^{n-k} \) and \( r \leftarrow \{0,1\}^{n-k} \), and sends \((h(x_1), \ldots, h(x_k), r, \langle r, x \rangle \oplus b)\) to the receiver. The min-entropy of \( x \), even given \( h(x_1), \ldots, h(x_k) \) is now \( \Omega(k) \), and the LHL now yields that the statistical distance between the two distributions \((h, h(x_1), \ldots, h(x_k), r, \langle r, x \rangle \oplus 0)\) and \((h, h(x_1), \ldots, h(x_k), r, \langle r, x \rangle \oplus 1)\) is roughly \( 2^{-k} \). Setting \( k \) to be sufficiently large (e.g., \( k = \text{poly}(n) \) or even \( k = \text{poly} \log(n) \)) we obtain that the scheme is statistically-hiding. Note that repetition also does not hurt binding: if the sender can find valid decommitments \((x = (x_1, \ldots, x_k), 0)\) and \((x' = (x'_1, \ldots, x'_k), 1)\) that pass the receiver’s verification, then there must exist \( i \in [k] \) with \( x_i \neq x'_i \) and \( h(x_i) = h(x'_i) \) (i.e., a collision).

Handling MCRHs. For simplicity, let us focus on the case \( t = 4 \) (since it basically incorporates all the difficulty encountered when dealing with larger values of \( t \)). That is, we assume that \( \mathcal{H} = \{ h : \{0,1\}^n \rightarrow \{0,1\}^{n-s} \} \) is an \((s, t)\)-MCRH with \( s = 2 \) and \( t = 4 \). Namely, it is hard to find \( 4 \) inputs that map to the same hash value for a random function from \( \mathcal{H} \), even though such 4-way collisions exist. Note however that it might very well be easy to find 3 such colliding inputs. And indeed, the binding argument that we had before breaks: finding \( x \neq x' \) with \( h(x) = h(x) \) is no longer (necessarily) a difficult task.

The problem comes up because even after the sender ‘commits’ to \( y_1 = h(x_1), \ldots, y_k = h(x_k) \), it is no longer forced to reveal \( x_1, \ldots, x_k \). Intuitively, for every \( y_i \), the sender might know \( 3 \) inputs that map to \( y_i \), so, the sender is free to reveal any value in the Cartesian product of these triples. Concretely, let \( \mathcal{S}_{y_i} \) be the set of inputs that \( h \) maps to \( y_i \) that the sender can find efficiently, and let \( \mathcal{S}_y = \mathcal{S}_{y_1} \times \cdots \times \mathcal{S}_{y_k} \). Since the sender can find at most \( 3 \) colliding inputs, it holds that \( |\mathcal{S}_{y_i}| \leq 3 \) for every \( i \), and thus \( |\mathcal{S}_y| \leq 3^k \). To fix the binding argument, we want to force every efficient sender to be able to reveal a unique \( x = (x_1, \ldots, x_k) \in \mathcal{S}_y \).

A first attempt toward achieving the above goal is to try to use a pairwise-independent hash function \( f \) that is injective over \( \mathcal{S}_y \) with high probability. At a high level, the receiver will also specify to the sender a random function \( f \) from the pairwise independent hash function family.
The sender in turn sends $f(x)$ as well as $(h(x_1), \ldots, h(x_k))$. The receiver adds a check to the verification step to ensure that $f$ maps the decommited input sequence $(x'_1, \ldots, x'_k)$ to the value that was pre-specified.

In order for the function $f$ to be injective on the set $S_Y$, the birthday paradox tells us that the range of $f$ must have size at least $|S_Y|^2$ (roughly), which means at least $3^{2k}$. Thus, to ensure that $f$ is injective on $S_Y$, we can use a pairwise-independent function $f: \{0,1\}^{nk} \rightarrow \{0,1\}^{2k\log(3)}$.

Unfortunately, this scheme is still not binding: $f$ is promised (with high probability) to be injective for fixed sets of size $3^k$, but the sender can choose $y$ based on the value of $f$. Specifically, to choose $y$ so that $f$ is not injective over $S_Y$. To fix the latter issue, we split the messages that the receiver sends into two rounds. In the first round the receiver sends $h$ and receives $y = (h(x_1), \ldots, h(x_k))$ from the sender. Only then the receiver sends $f$ and receives $z_1 = f(x)$. Now, the scheme is binding: since $f$ is chosen after $y$ is set, the pairwise-independence property guarantees that $f$ will be injective over $S_Y$ with high probability. Pictorially, the commit stage of the new scheme is as follows:

\[
\begin{array}{c}
\text{S(b)} \\
\hline
x \leftarrow \{0,1\}^{nk}, \\
y_i = h(x_i) \\
\end{array}
\quad
\begin{array}{c}
\text{R} \\
\hline
h \\
y = (y_1, y_2 \ldots y_k) \\
f \\
r \leftarrow \{0,1\}^{nk} \\
f(x), r, \langle r, x \rangle \oplus b
\end{array}
\]

But is this scheme statistically-hiding? Recall that previously, to argue hiding, we used the fact that the mapping $(x_1, \ldots, x_k) \mapsto (h(x_1), \ldots, h(x_k))$ is shrinking. Analogously here, we need the mapping $(x_1, \ldots, x_k) \mapsto (h(x_1), \ldots, h(x_k), f(x))$ to be shrinking. However, the latter mapping maps strings of length $n \cdot k$ bits to strings of length $(n - 2) \cdot k + 2 \log(3) \cdot k$, which is obviously not shrinking.

One work-around is to simply assume that the given MCRH shrinks much more than we assumed so far. For example, to assume that $H$ is $(4,4)$-MCRH (or more generally $(s,t)$-MCRH for $s \gg \log(t)$).

However, by adding one more round of interaction we can actually fix the protocol so that it gives statistically-hiding commitments even with tight shrinkage of $\log(t)$.

**Overcoming the Birthday Paradox.** To guarantee hiding, it seems that we cannot afford the range of $f$ to be as large as $(3^k)^2$. Instead, we set its range size to $3^k$ (i.e., $f: \{0,1\}^{nk} \rightarrow \{0,1\}^{k\log(3)}$). Moreover, rather than choosing it from a pairwise independent hash function family, we shall one more use one that is many-wise-independent. Again, the important property that we use is that such functions are load-balanced with high probability, $z_1$ — the value that the sender sends in the second round — has at most $\log(3^k) = k \cdot \log(3)$ pre-images from $S_Y$ under $f$ (i.e.,

---

\footnote{We remark that our construction of MCRH based on $\text{EA}_{\min,\max}$ (see Section 3) actually supports such large shrinkage.}

\footnote{In a nutshell, the property that we are using is that if $N = 3^k$ balls are thrown into $N$ bins, with high probability the maximal load in every bin will be at most $\log(N)$. It is well-known that hash functions that are $\log(N)$-wise independent also have this property. See Section 2.2 for details.}

---

10
\[\{x \in S_v : f(x) = z_1\} \leq k \cdot \log(3)\]. We once more face the problem that the sender can reveal any of these inputs, but now their number is exponentially smaller — it is only \(k \log(3)\) (as opposed to \(3^k\) before). We can now choose a pairwise-independent \(g: \{0,1\}^{nk} \rightarrow \{0,1\}^{2(\log(k) + \log\log(3))}\) that is injective over sets of size \(k \cdot \log(3)\) (with high probability). For the same reasons that \(f\) was sent after \(h\), the receiver sends \(g\) only after receiving \(f(x)\).

Thus, our final protocol has three rounds (where each round is composed of one message for each of the two parties) and is as follows: In the first round, the receiver selects \(h \leftarrow H\) and sends it to the sender. The sender, trying to commit to a bit \(b\), chooses \(x = (x_1, \ldots, x_k) \leftarrow \{0,1\}^{nk}\) and sends \(y = (y_1 = h(x_1), \ldots, y_k = h(x_k))\). In the second round, the receiver selects a many-wise-independent hash function \(f: \{0,1\}^{nk} \rightarrow \{0,1\}^{k \log(3)}\) and sends it to the sender. The sender sends \(z_1 = f(x)\) to the receiver. In the third and final round, the receiver selects a pairwise-independent hash function \(g: \{0,1\}^{nk} \rightarrow \{0,1\}^{2(\log(k) + \log\log(3))}\) and sends it to the sender. The sender selects \(r \leftarrow \{0,1\}^{nk}\), and sends \((z_2 = g(x), r, \sigma = \langle r, x \rangle \oplus b)\) to the receiver. The commitment is defined as \(c = (h, y, f, z_1, g, z_2, \sigma)\). To reveal, the sender sends \((x, b)\) to the receiver, which verifies that \(h(x_i) = y_i\) for every \(i\), that \(f(x) = z_1\), \(g(x) = z_2\) and \(\sigma = \langle r, x \rangle \oplus b\). Pictorially, the commit stage is as follows:

\[
\begin{array}{ccc}
\text{S(b)} & \quad h & \quad R \\
\hline \\
x \leftarrow \{0,1\}^{nk}, & f & g \\
y_i = h(x_i), & f(x) & g : \{0,1\}^{nk} \rightarrow \{0,1\}^{2(\log(k) + \log\log(3))} \\
 & & \\
h \leftarrow \text{Gen}(1^n) \\
 & & \\
r \leftarrow \{0,1\}^{nk}, & g(x), r, \langle r, x \rangle \oplus b \\
 & & \\
\end{array}
\]

Intuitively, the scheme is computationally-binding since for any computationally-bounded sender that committed to \(c\), there is a unique \(x\) that passes the receiver’s verification. As for hiding, we need the mapping \((x_1, \ldots, x_k) \mapsto (h(x_1), \ldots, h(x_k), f(x), g(x))\) to be shrinking. Observe that we are mapping \(n \cdot k\) bits to \((n - 2)k + \log(3)k + 2(\log(k) + \log\log(3))\) bits (where all logarithms are to the base 2). Choosing \(k\) to be sufficiently large (e.g., \(k = \text{poly}(n)\) certainly suffices) yields that the mapping is shrinking.

This completes the high level overview of the direct analysis of our construction of constant-round statistically hiding commitments. The formal proof, done via a reduction from the binding of the scheme to the MCRH property, requires more delicate care (and in particular handling certain probabilistic dependencies that arise in the reduction). See Section 4 for details.

### 1.3.2.2 Analysis via Inaccessible Entropy

Consider the jointly distributed random variables \((h(x), x)\), where \(h\) is chosen at random from a family of \(t\)-way collision resistant hash functions \(\mathcal{H} = \{h: \{0,1\}^n \rightarrow \{0,1\}^{n - \log(t)}\}\) and \(x\) is a
uniform $n$-bit string. Since $h(x)$ is only $(n - \log(t))$ bits long, it can reveal only that amount of information about $x$. Thus, the entropy of $x$ given $h(x)$ (and $h$) is at least $\log(t)$. In fact, a stronger property holds: the expected number of pre-images of $h(x)$, over the choice of $x$, is $t$. This implies that $x$ given $h(x)$ has $\log(t)$ bits of (a weaker variant of) min-entropy.

While $h(x)$ has $t$ pre-images (in expectation), no efficient strategy can find more than $t - 1$ of them. Indeed, efficiently finding $t$ such (distinct) pre-images directly violates the $t$-way collision resistance of $h$.

In terms of inaccessible entropy, the above discussion establishes that $(h(x), x)$ is a 2-block inaccessible entropy generator where the second block (i.e., $x$) has real min-entropy $\log(t)$ and accessible max-entropy at most $\log(t - 1)$. This block generator is not quite sufficient to get statistically-hiding commitment since the construction of \cite{HRVW09, HV17} requires a larger gap between the entropies. This, however, is easily solved since taking many copies of the same generator increases the entropy gap. That is, the final 2-block generator is $(h(x_1), \ldots, h(x_k)), (x_1, \ldots, x_k)$, for a suitable choice of $k$. The existence of constant-round statistically-hiding commitment now follows immediately from \cite[Lemma 19]{HV17}.\footnote{The general construction of statistically-hiding commitments from inaccessible entropy generators is meant to handle a much more general case than the one needed in our setting. In particular, a major difficulty handled by \cite{HRVW09, HV17} is when the generator has many blocks and it is not known in which one there is a gap between the real and accessible entropies.} The resulting protocol turns out to be essentially the same as that obtained by the direct analysis discussed above (and proved in Section 4).

1.4 Organization

In Section 2 we provide standard definitions and basic facts. In Section 3 we formally state the entropy approximation assumption and present our construction of MCRH based on this assumption. In Section 4 we describe the construction of constant-round statistically-hiding commitments from MCRH. Lastly, in Section 5 we prove the blackbox separation of MCRH from one-way permutations.

2 Preliminaries

We use lowercase letters for values, uppercase for random variables, uppercase calligraphic letters (e.g., $\mathcal{U}$) to denote sets, boldface for vectors (e.g., $\mathbf{x}$), and uppercase sans-serif (e.g., $\mathbb{A}$) for algorithms (i.e., Turing Machines). All logarithms considered here are in base two. We let $\text{poly}$ denote the set of all polynomials. A function $\nu : \mathbb{N} \rightarrow [0, 1]$ is negligible, denoted $\nu(n) = \text{negl}(n)$, if $\nu(n) < 1/p(n)$ for every $p \in \text{poly}$ and large enough $n$.

Given a random variable $X$, we write $x \leftarrow X$ to indicate that $x$ is selected according to $X$. Similarly, given a finite set $\mathcal{S}$, we let $s \leftarrow \mathcal{S}$ denote that $s$ is selected according to the uniform distribution on $\mathcal{S}$. We adopt the convention that when the same random variable occurs several times in an expression, all occurrences refer to a single sample. For example, $\Pr[f(X) = X]$ is defined to be the probability that when $x \leftarrow X$, we have $f(x) = x$. We write $U_n$ to denote the random variable distributed uniformly over $\{0, 1\}^n$. The support of a distribution $D$ over a finite set $\mathcal{U}$, denoted $\text{Supp}(D)$, is defined as $\{u \in \mathcal{U} : D(u) > 0\}$. The statistical distance of two distributions $P$ and $Q$ over a finite set $\mathcal{U}$, denoted $\text{SD}(P, Q)$, is defined as $\max_{\mathcal{S} \subseteq \mathcal{U}} |P(\mathcal{S}) - Q(\mathcal{S})| = \frac{1}{2} \sum_{u \in \mathcal{U}} |P(u) - Q(u)|$.\footnote{The general construction of statistically-hiding commitments from inaccessible entropy generators is meant to handle a much more general case than the one needed in our setting. In particular, a major difficulty handled by \cite{HRVW09, HV17} is when the generator has many blocks and it is not known in which one there is a gap between the real and accessible entropies.}
2.1 Many-wise Independent Hashing

Many-wise independent hash functions are used extensively in complexity theory and cryptography.

**Definition 2.1** ($ℓ$-wise Independent Hash Functions). For $ℓ \in \mathbb{N}$, a family of functions $\mathcal{F} = \{ f : \{0,1\}^n \rightarrow \{0,1\}^m \}$ is $ℓ$-wise independent if for every distinct $x_1, x_2, \ldots, x_\ell \in \{0,1\}^n$ and every $y_1, y_2, \ldots, y_\ell \in \{0,1\}^m$, it holds that

$$\Pr_{f \leftarrow \mathcal{F}}[f(x_1) = y_1 \land f(x_2) = y_2 \land \cdots \land f(x_\ell) = y_\ell] = \frac{1}{M^\ell}.$$ 

Note that if $\mathcal{H}$ is $k$-wise independent for $k \geq 2$, it is also universal. The existence of efficient many-wise hash function families is well known.

**Fact 2.2** (c.f. [Vad12, Corollary 3.34]). For every $n, m, \ell \in \mathbb{N}$, there exists a family of $\ell$-wise independent hash functions $\mathcal{F}_{n,m}^{(\ell)} = \{ f : \{0,1\}^n \rightarrow \{0,1\}^m \}$ where a random function from $\mathcal{F}_{n,m}^{(\ell)}$ can be selected using $\ell \cdot \max(m, n)$ bits, and given a description of $f \in \mathcal{F}_{n,m}^{(\ell)}$ and $x \in \{0,1\}^n$, the value $f(x)$ can be evaluated in time $\text{poly}(n, m, \ell)$.

Whenever we only need pairwise independent hash function $\mathcal{F}_{n,m}^{(2)}$, we remove the two from the superscript and simply write $\mathcal{F}_{n,m}$.

2.2 Load Balancing

The theory of load balancing deals with allocating elements into bins, such that no bin has too many elements. If the allocation is done at random, it can be shown that with high probability the max load (i.e., the number of elements in the largest bin) is not large. In fact, allocating via many-wise independent hash function also suffices.

**Fact 2.3** (Folklore (see, e.g., [CRSW13])). Let $n, m, \ell \in \mathbb{N}$ with $\ell \geq 2e$ (where $e$ is the base of the natural logarithm) and let $\mathcal{F}_{n,m}^{(\ell)}$ be an $\ell$-wise independent hash function family. Then, for every set $S \subseteq \{0,1\}^n$ with $|S| \leq 2^m$ it holds that:

$$\Pr_{f \leftarrow \mathcal{F}_{n,m}^{(\ell)}}[\exists y \in \{0,1\}^m \text{ such that } |f^{-1}(y) \cap S| \geq \ell] \leq 2^{m-\ell},$$

where $f^{-1}(y) = \{x \in \{0,1\}^n : f(x) = y\}$.

**Proof.** Fix $y \in \{0,1\}^m$. It holds that

$$\Pr_{f \leftarrow \mathcal{F}_{n,m}^{(\ell)}}[f^{-1}(y) \cap S \geq \ell] \leq \Pr_{f \leftarrow \mathcal{F}_{n,m}^{(\ell)}}[\exists \text{ distinct } x_1, \ldots, x_\ell \in S : f(x_1) = y \land \cdots \land f(x_\ell) = y]$$

$$\leq \sum_{\text{distinct } x_1, \ldots, x_\ell \in S} \Pr_{f \leftarrow \mathcal{F}_{n,m}^{(\ell)}}[f(x_1) = y \land \cdots \land f(x_\ell) = y]$$

$$\leq \left(\frac{2^m}{\ell}\right) \cdot \left(\frac{1}{2^m}\right)^\ell$$

$$\leq \left(\frac{e \cdot 2^m}{\ell}\right) \cdot \left(\frac{1}{2^m}\right)^\ell$$

$$\leq 2^{-\ell},$$

13
where the second inequality is by a union bound, the third inequality follows from the $\ell$-wise independence of $F^{(\ell)}_{n,m}$, the fourth inequality is by a standard bound on binomial coefficients, and the last inequality follows by our assumption that $\ell \geq 2e$.

Fact 2.3 follows from a union bound over all values of $y \in \{0,1\}^m$. 

**Remark 2.4 (More Efficient Hash Functions).** We remark that more efficient constructions of hash functions guaranteeing the same load balancing performance as in Fact 2.3 are known in the literature.

Specifically, focusing on the setting of $\ell = O(m)$, Fact 2.3 gives a load balancing guarantee for functions whose description size (i.e., key length) is $\Omega(m^2)$ bits. In contrast, a recent result of Celis et al. [CRSW13] constructs such functions that require only $\tilde{O}(m)$ key size. Furthermore, a follow up work of Meka et al. [MRRR14] improves the evaluation time of the [CRSW13] hash function to be only poly-logarithmic in $m$ (in the word RAM model).

However, since our focus is not on concrete efficiency, we ignore these optimizations throughout this work.

3 Constructing MCRH Families

In this section, we present a construction of a Multi-Collision Resistant Hash family (MCRH) based on the hardness of estimating certain notions of entropy of a distribution, given an explicit description of the distribution (i.e., a circuit that generates it). We define and discuss this problem in Section 3.1, and present the construction of MCRH in Section 3.2.

3.1 Entropy Approximation

In order to discuss the problem central to our construction, we first recall some standard notions of entropy.

**Definition 3.1.** For a random variable $X$, we define the following notions of entropy:

- **Min-entropy**: $H_{\text{min}}(X) = \min_{x \in \text{Supp}(X)} \log \left( \frac{1}{Pr[X=x]} \right)$.
- **Max-entropy**: $H_{\text{max}}(X) = \log (|\text{Supp}(X)|)$.
- **Shannon entropy**: $H_{\text{Shannon}}(X) = E_{x \leftarrow X} \left[ \log \left( \frac{1}{Pr[X=x]} \right) \right]$.

For any random variable, these entropies are related as described below. These relations ensure that the problems we describe later are well-defined.

**Fact 3.2.** For a random variable $X$ supported over $\{0,1\}^m$,

$$0 \leq H_{\text{min}}(X) \leq H_{\text{Shannon}}(X) \leq H_{\text{max}}(X) \leq m.$$

Given a circuit $C : \{0,1\}^n \to \{0,1\}^m$, we overload $C$ to also denote the random variable induced by evaluating $C$ on a uniformly random input from $\{0,1\}^n$. With this notation, the Entropy Approximation problem is defined as below.
Definition 3.3 (Min-Max Entropy Approximation). Let $g = g(n) \in \mathbb{R}$ be a function such that $0 < g(n) < n$. The min-max Entropy Approximation problem with gap $g$, denoted $\text{EA}_{\min,\max}^{(g)}$, is a promise problem $(\text{YES}, \text{NO})$ for YES = \{YES\}_{n \in \mathbb{N}} and NO = \{NO\}_{n \in \mathbb{N}}$, where we define

$$
\begin{align*}
\text{YES}_n &= \{(1^n, C_n, k) : H_{\min}(C_n) \geq k\}, \\
\text{NO}_n &= \{(1^n, C_n, k) : H_{\max}(C_n) \leq k - g(n)\},
\end{align*}
$$

and where in both cases $C_n$ is a circuit that takes $n$ bits of input, and $k \in \{0, \ldots, n\}$.

We also define $\text{EA}_{\min,\max}^{(1)} = \text{EA}_{\min,\max}^{(1)}$. That is, when we omit the gap $g$ we simply mean that $g = 1$.

The Shannon Entropy Approximation problem (where $H_{\min}$ and $H_{\max}$ above are replaced with $H_{\text{Shannon}}$), with constant gap, was shown by Goldreich et al. [GSV99] to be complete for the class NISZK (promise problems with non-interactive statistical zero knowledge proof systems). For a discussion of generalizations of Entropy Approximation to other notions of entropy, and other related problems, see [DGRV11].

3.1.1 The Assumption: Average-Case Hardness of Entropy Approximation

Our construction of MCRH is based on the average-case hardness of the Entropy Approximation problem $\text{EA}_{\min,\max}$ defined above (i.e., with gap 1). We use the following definition of average-case hardness of promise problems.

Definition 3.4 (Average-case Hardness). We say that a promise problem $\Pi = (\text{YES}, \text{NO})$, where YES = \{YES\}_{n \in \mathbb{N}} and NO = \{NO\}_{n \in \mathbb{N}} is average-case hard if there is a probabilistic algorithm $S$ such that $S(1^n)$ outputs samples from $(\text{YES}_n \cup \text{NO}_n)$, and for every family of polynomial-sized circuits $A = (A_n)_{n \in \mathbb{N}}$,

$$
\Pr_{x \leftarrow S(1^n)}[A_n(x) = \Pi(x)] \leq \frac{1}{2} + \text{negl}(n),
$$

where $\Pi(x) = 1$ if $x \in \text{YES}$ and $\Pi(x) = 0$ if $x \in \text{NO}$. We call $S$ a hard-instance sampler for $\Pi$. The quantity $(Pr_{x \leftarrow S(1^n)}[A_n(x) = \Pi(x)] - 1/2)$ is referred to as the advantage the algorithm $A$ has in deciding $\Pi$ with respect to the sampler $S$.

In our construction and proofs, it will be convenient for us to work with the problem $\text{EA}_{\min,\max}^{(\lceil \sqrt{n} \rceil)}$ rather than $\text{EA}_{\min,\max}^{(1)}$. At first glance $\text{EA}_{\min,\max}^{(\lceil \sqrt{n} \rceil)}$ seems to be an easier problem because the gap here is $\lceil \sqrt{n} \rceil$, which is much larger. The following simple proposition shows that these two problems are in fact equivalent (even in their average-case complexity). The key idea here is repetition: given a circuit $C$, we can construct a new circuit $C'$ that outputs $C$ evaluated on independent inputs with a larger gap.

Proposition 3.5. $\text{EA}_{\min,\max}^{(\lceil \sqrt{n} \rceil)}$ is average-case hard if and only if $\text{EA}_{\min,\max}^{(1)}$ is average-case hard.

Proof Sketch. Any YES instance of $\text{EA}_{\min,\max}^{(\lceil \sqrt{n} \rceil)}$ is itself a YES instance of $\text{EA}_{\min,\max}^{(1)}$, and the same holds for NO instances. So the average-case hardness of $\text{EA}_{\min,\max}^{(\lceil \sqrt{n} \rceil)}$ immediately implies that of
The Construction of MCRH

Let $S$ be a hard-instance sampler for $\text{EA}_{\min, \max}^\left(\lfloor \sqrt{n} \rfloor \right)$.

\text{Gen}(1^n):

1. Sample $(1^n, C_n, k) \leftarrow S(1^n)$, where $C_n$ maps $\{0, 1\}^n \rightarrow \{0, 1\}^{n'}$.
2. Sample $f \leftarrow F_{n,(n-k)}^{(3nn)}$ and $g \leftarrow F_{(n'-n-k),(n'-\lfloor \sqrt{n} \rfloor)}^{(2n)}$.
3. Output the circuit that computes the function $h_{C_n,f,g} : \{0, 1\}^n \rightarrow \{0, 1\}^{n-\lfloor \sqrt{n} \rfloor}$ that is defined as follows:

$$h_{C_n,f,g}(x) := g(C_n(x), f(x)).$$

\footnote{Recall that $F_{n,m}^{(\ell)} = \{f : \{0, 1\}^n \rightarrow \{0, 1\}^m\}$ is a family of $\ell$-wise independent hash functions.}

Figure 1: Construction of MCRH from Entropy Approximation.

$\text{EA}_{\min, \max}^\left(1\right)$, with the same hard-instance sampler. In order to show the implication in the other direction, we show how to use a hard-instance sampler for $\text{EA}_{\min, \max}^\left(1\right)$ to construct a hard-instance sampler $S'$ for $\text{EA}_{\min, \max}^\left(\lfloor \sqrt{n} \rfloor \right)$.

$S'$ on input $(1^n)$:

1. Let $\ell = \lfloor \sqrt{n} \rfloor$. $S'$ samples $(1^\ell, C_\ell, k) \leftarrow S(1^\ell)$.
2. Let $\tilde{C}_n$ be the following circuit that takes an $n$-bit input $x$. It breaks $x$ into $\ell + 1$ disjoint blocks $x_1, \ldots, x_{\ell+1}$, where $x_1, \ldots, x_\ell$ are of size $\ell$, and $x_{\ell+1}$ is whatever remains. It ignores $x_{\ell+1}$, runs a copy of $C_\ell$ on each of the other $x_i$'s, and outputs a concatenation of all the outputs.
3. $S'$ outputs $(1^n, \tilde{C}_n, k \cdot \ell)$.

As $\tilde{C}_n$ is the $\ell$-fold repetition of $C_\ell$, its max and min entropies are $\ell$ times the respective entropies of $C_\ell$. So if $C_\ell$ had min-entropy at least $k$, then $\tilde{C}_n$ has min-entropy at least $k \cdot \ell$, and if $C_\ell$ had max-entropy at most $(k - 1)$, then $\tilde{C}_n$ has max-entropy at most $(k - 1) \cdot \ell = k \cdot \ell - \ell$, where $\ell = \lfloor \sqrt{n} \rfloor$. The proposition follows.

3.2 The Construction

Our construction of a Multi-Collision Resistant Hash (MCRH) family is presented in Figure 1. We now prove that the construction is secure under our average-case hardness assumption.

\textbf{Theorem 3.6.} If $\text{EA}_{\min, \max}^\left(\lfloor \sqrt{n} \rfloor \right)$ is average-case hard, then the construction in Figure 1 is an $(s, t)$-MCRH, where $s = \lfloor \sqrt{n} \rfloor$ and $t = 6n^2$.

The above theorem, along with Proposition 3.5, now implies the following.

\textbf{Corollary 3.7.} If $\text{EA}_{\min, \max}$ is average-case hard, then there exists an $(s, t)$-MCRH, where $s = \lfloor \sqrt{n} \rfloor$ and $t = 6n^2$.  

16
Note that above, the shrinkage being \(\sqrt{n}\) guarantees that there exist \(2^{\sqrt{n}}\)-way collisions. But the construction is such that it is not possible to find even a \(6n^2\)-way collision, (which is sub-exponentially smaller). This is significant because, unlike in the case of standard collision-resistant hash functions (i.e., in which it is hard to find a pair of collisions), shrinkage in MCRHs cannot be easily amplified by composition while maintaining the same amount of collision-resistance (see Remark 1.2).

The rest of this section is dedicated to proving Theorem 3.6.

**Proof of Theorem 3.6.** Let \(\text{Gen}\) denote the algorithm described in Figure 1, and \(S\) be the hard-instance sampler used there. Fact 2.2, along with the fact that \(S\) runs in polynomial-time ensures that \(\text{Gen}\) runs in polynomial-time as well. The shrinkage requirement of an MCRH is satisfied because here the shrinkage is \(s(n) = \sqrt{n}\). To demonstrate multi-collision resistance, we show how to use an adversary that finds \(6n^2\) collisions in hash functions sampled by \(\text{Gen}\) to break the average-case hardness of \(\text{EA}_{\min,\max}(\sqrt{n})\). For the rest of the proof, to avoid cluttering up notations, we will denote the problem \(\text{EA}_{\min,\max}(\sqrt{n})\) by just \(\text{EA}\).

We begin with an informal discussion of the proof. We first prove that large sets of collisions that exist in a hash function output by \(\text{Gen}\) have different properties depending on whether the instance that was sampled in step 1 of \(\text{Gen}\) was a YES or NO instance of \(\text{EA}\). Specifically, notice that the hash functions that are output by \(\text{Gen}\) have the form \(h_{C_n,f,g}(x) = g(C_n(x), f(x))\); we show that, except with negligible probability:

- In functions \(h_{C_n,f,g}\) generated from \((1^n, C_n, k) \in \text{YES}\), with high probability, there do not exist \(3n\) distinct inputs \(x_1, \ldots, x_{3n}\) such that they all have the same value of \((C_n(x_i), f(x_i))\).

- In functions \(h_{C_n,f,g}\) generated from \((1^n, C_n, k) \in \text{NO}\), with high probability, there do not exist \(2n\) distinct inputs \(x_1, \ldots, x_{2n}\) such that they all have distinct values of \((C_n(x_i), f(x_i))\), but all have the same value \(g(C_n(x_i), f(x_i))\).

Note that in any set of \(6n^2\) collisions for \(h_{C_n,f,g}\), there has to be either a set of \(3n\) collisions for \((C_n, f)\) or a set of \(2n\) collisions for \(g\), and so at least one of the conclusions in the above two statements is violated.

A candidate average-case solver for \(\text{EA}\), when given an instance \((1^n, C_n, k)\), runs steps 2 and 3 of the algorithm \(\text{Gen}\) from Figure 1 with this \(C_n\) and \(k\). It then runs the collision-finding adversary on the hash function \(h_{C_n, f, g}\) that is thus produced. If the adversary does not return \(6n^2\) collisions, it outputs a uniformly random answer. But if these many collisions are returned, it checks which of the conclusions above is violated, and thus knows whether it started with a YES or NO instance. So whenever the adversary succeeds in finding collisions, the distinguisher can decide \(\text{EA}\) correctly with overwhelming probability. As long as the collision-finding adversary succeeds with non-negligible probability, then the distinguisher also has non-negligible advantage, contradicting the average-case hardness of \(\text{EA}\).

We now state and prove the above claims about the properties of sets of collisions, then formally write down the adversary outlined above and prove that it breaks the average case hardness of \(\text{EA}\).

The first claim is that for hash functions \(h_{C_n,f,g}\) generated according to \(\text{Gen}\) using a YES instance, there is no set of \(3n\) distinct \(x_i\)’s that all have the same value for \(C_n(x_i)\) and \(f(x_i)\), except with negligible probability.
Claim 3.7.1. Let \((1^n, C_n, k)\) be a YES instance of \(\text{EA}\). Then,

\[
\Pr_{f \leftarrow \mathcal{F}^{(3n)}_{n,(n-k)}} \left[ \exists y, y_1 \in \{0,1\}^* : |C_n^{-1}(y) \cap f^{-1}(y_1)| \geq 3n \right] \leq \frac{1}{2^n}.
\]

Intuitively, the reason this should be true is that when \(C_n\) comes from a YES instance, it has high min-entropy. This means that for any \(y\), the set \(C_n^{-1}(y)\) will be quite small. The function \(f\) can now be thought of as partitioning each set \(C_n^{-1}(y)\) into several parts, none of which will be too large because of the load-balancing properties of many-wise independent hash functions.

Proof. The above probability can be bounded using the union bound as follows:

\[
\Pr_f \left[ \exists y, y_1 : |C_n^{-1}(y) \cap f^{-1}(y_1)| \geq 3n \right] \leq \sum_{y \in \text{Im}(C_n)} \Pr_f \left[ \exists y_1 : |C_n^{-1}(y) \cap f^{-1}(y_1)| \geq 3n \right]. \tag{1}
\]

The fact that \((1^n, C_n, k)\) is a YES instance of \(\text{EA}\) means that \(H_{\text{min}}(C_n) \geq k\). The definition of min-entropy now implies that for any \(y \in \text{Im}(C_n)\):

\[
\log \left( \frac{1}{\Pr_{x \sim \{0,1\}^n}[C_n(x) = y]} \right) \geq k,
\]

which in turn means that \(|C_n^{-1}(y)| \leq 2^{n-k}\). Fact 2.3 (about the load-balancing properties of \(\mathcal{F}^{(3n)}_{n,(n-k)}\)) now implies that for any \(y \in \text{Im}(C_n)\):

\[
\Pr_f \left[ \exists y_1 : |C_n^{-1}(y) \cap f^{-1}(y_1)| \geq 3n \right] \leq \frac{2^{n-k}}{2^{3n}} \leq \frac{1}{2^n}. \tag{2}
\]

Combining Eqs. (1) and (2), and noting that the image of \(C_n\) has at most \(2^n\) elements, we get the desired bound:

\[
\Pr_f \left[ \exists y, y_1 : |C_n^{-1}(y) \cap f^{-1}(y_1)| \geq 3n \right] \leq 2^n \cdot \frac{1}{2^n} = \frac{1}{2^n}.
\]

\(\square\)

The next claim is that for hash functions \(h_{C_n,f,g}\) generated according to \(\text{Gen}\) using a NO instance, there is no set of \(2^n\) values of \(x_i\) that all have distinct values of \((C_n(x_i), f(x_i))\), but the same value \(g(C_n(x_i), f(x_i))\), except with negligible probability.

Claim 3.7.2. Let \((1^n, C_n, k)\) be a NO instance of \(\text{EA}\). Then,

\[
\Pr_{\substack{f \leftarrow \mathcal{F}^{(3n)}_{n,(n-k)} \\ g \leftarrow \mathcal{F}^{(2n)}_{n'(n-k), (n-\lfloor \sqrt{n} \rfloor)}}} \left[ \exists x_1, \ldots, x_{2^n} : \begin{array}{l}
\text{For all } i \neq j, \ (C_n(x_i), f(x_i)) \neq (C_n(x_j), f(x_j)), \text{ and } \\
g(C_n(x_i), f(x_i)) = g(C_n(x_j), f(x_j))
\end{array} \right] \leq \frac{1}{2^n}.
\]

Proof. The fact that \((1^n, C_n, k)\) is a NO instance of \(\text{EA}\) means that \(H_{\text{max}}(C_n) \leq k - \lfloor \sqrt{n} \rfloor\); that is, \(C_n\) has a small range: \(|\text{Im}(C_n)| \leq 2^{k-\lfloor \sqrt{n} \rfloor} \).
For any \( f \in \mathcal{F}_{n(n-k)}^{(3n)} \), which is what is sampled by \textsc{Gen} when this instance is used, the range of \( f \) is a subset of \( \{0, 1\}^{n-k} \). This implies that even together, \( C_n \) and \( f \) have a range whose size is bounded as:

\[
|\text{Im}(C_n, f)| \leq 2^{k-\lceil \sqrt{n} \rceil} \cdot 2^{n-k} = 2^{n-\lceil \sqrt{n} \rceil},
\]

where \((C_n, f)\) denotes the function that is the concatenation of \( C_n \) and \( f \).

For there to exist a set of \( 2n \) inputs \( x_i \) that all have distinct values for \((C_n(x_i), f(x_i))\) but the same value for \( g(C_n(x_i), f(x_i)) \), there has to be a \( y \) that has more than \( 2n \) inverses under \( g \) that are all in the image of \((C_n, f)\). As \( g \) comes from \( \mathcal{F}_{n'+n-k}^{(2n)} \), we can use Fact 2.3 along with the above bound on the size of the image of \((C_n, f)\) to bound the probability that such a \( y \) exists as follows:

\[
\Pr_y \left[ \exists y : \left| g^{-1}(y) \cap \text{Im}(C_n, f) \right| \geq 2n \right] \leq \frac{2^{n-\lceil \sqrt{n} \rceil}}{2^{2n}} \leq \frac{1}{2^n}.
\]

Let \( A = (A_n)_{n \in \mathbb{N}} \) be a polynomial-size family of circuits that given a hash function output by \textsc{Gen}(1\(^n\)) finds a \( 6n^2 \)-way collision in it with non-negligible probability. The candidate circuit family \( A' = (A'_n)_{n \in \mathbb{N}} \) for solving \( \text{EA} \) on average is described below.

\( A'_n \) on input \((1^n, C_n, k)\):

1. Run steps 2 and 3 of the algorithm \textsc{Gen} in Figure 1 with \((1^n, C_n, k)\) in place of the instance sampled from \( S \) there. This results in the description of a hash function \( h_{C_n,f,g} \).
2. Run \( A_n(h_{C_n,f,g}) \) to get a set of purported collisions \( S \).
3. If \( S \) does not actually contain \( 6n^2 \) collisions under \( h_{C_n,f,g} \), output a random bit.
4. If \( S \) contains \( 3n \) distinct \( x_i \)'s such that they all have the same value of \((C_n(x_i), f(x_i))\), output 0.
5. If \( S \) contains \( 2n \) distinct \( x_i \)'s such that they all have distinct values of \((C_n(x_i), f(x_i))\) but the same value \( g(C_n(x_i), f(x_i)) \), output 1.

The following claim now states that any collision-finding adversary for the MCRH constructed can be used to break the average-case hardness of \( \text{EA} \), thus completing the proof.

**Claim 3.7.3.** If \( A \) finds \( 6n^2 \) collisions in hash functions output by \textsc{Gen}(1\(^n\)) with non-negligible probability, then \( A' \) has non-negligible advantage in deciding \( \text{EA} \) with respect to the hard-instance sampler \( S \) used in \textsc{Gen}.

**Proof.** On input \((1^n, C_n, k)\), the adversary \( A'_n \) computes \( h_{C_n,f,g} \) and runs \( A_n \) on it. If \( A_n \) does not find \( 6n^2 \) collisions for \( h_{C_n,f,g} \), then \( A'_n \) guesses at random and is correct in its output with probability \( 1/2 \). If \( A_n \) does find \( 6n^2 \) collisions, then \( A'_n \) is correct whenever one of the following is true:

1. \((1^n, C_n, k)\) is a YES instance and there is no set of \( 3n \) collisions for \((C_n, f)\).
2. \((1^n, C_n, k)\) is a NO instance and there is no set of \(2n\) collisions for \(g\) in the image of \((C_n, f)\).

Note that inputs to \(A'_n\) are drawn from \(S(1^n)\), and so the distribution over \(h_{C_n,f,g}\) produced by \(A'_n\) is the same as that produced by \(\text{Gen}(1^n)\) itself. With such samples, let \(E_1\) denote the event of \((C_n, f)\) having a set of \(3n\) collisions from \(S\) (the set output by \(A_n\)), and let \(E_2\) denote the event of \(g\) having a set of \(2n\) collisions in the image of \((C_n, f)\) from \(S\). Also, let \(E_Y\) denote the event of the input to \(A'_n\) being a YES instance, \(E_N\) that of it being a NO instance, and \(E_A\) the event that \(S\) contains at least \(6n^2\) collisions.

Following the statements above, the probability that \(A'_n\) is wrong in deciding \(E_A\) with respect to \((1^n, C_n, k) \leftarrow S(1^n)\) can be upper-bounded as:

\[
\Pr[\text{A}'_n(1^n, C_n, k) \text{ is wrong}] \leq \Pr[\neg E_A] \cdot \frac{1}{2} + \Pr[(E_Y \land E_1) \lor (E_N \land E_2)].
\]

The first term comes from the fact that if \(A_n\) doesn’t find enough collisions, \(A'_n\) guesses at random. The second term comes from the fact that if both \((E_Y \land E_1)\) and \((E_N \land E_2)\) are false and \(E_A\) is true, then since at least one of \(E_Y\) and \(E_N\) is always true, one of \((E_Y \land \neg E_1)\) and \((E_N \land \neg E_2)\) will also be true, either of which would ensure that \(A'_n\) is correct, as noted earlier.

We now bound the second term above, starting as follows:

\[
\Pr[(E_Y \land E_1) \lor (E_N \land E_2)] \leq \Pr[(E_Y \land E_1)] + \Pr[(E_N \land E_2)] = \Pr[E_Y] \Pr[E_1|E_Y] + \Pr[E_N] \Pr[E_2|E_N] \leq \Pr[E_Y] \cdot \text{negl}(n) + \Pr[E_N] \cdot \text{negl}(n) = \text{negl}(n),
\]

where the first inequality follows from the union bound and the last inequality follows from Claims 3.7.1 and 3.7.2.

Putting this back in the earlier expression,

\[
\Pr[A'_n(1^n, C_n, k) \text{ is wrong}] \leq \Pr[\neg E_A] \cdot \frac{1}{2} + \text{negl}(n) = \frac{1}{2} - \frac{\Pr[E_A]}{2} + \text{negl}(n).
\]

In other words,

\[
\Pr[A'_n(1^n, C_n, k) \text{ is correct}] \geq \frac{1}{2} + \frac{\Pr[E_A]}{2} - \text{negl}(n).
\]

So if \(A\) succeeds with non-negligible probability in finding \(6n^2\) collisions, then \(A'\) had non-negligible advantage in deciding \(E_A\) over \(S\).

This concludes the proof of Theorem 3.6.

\(\square\)
4 Constant-Round Statistically-Hiding Commitments

In this section we show that multi-collision-resistant hash functions imply the existence of constant-round statistically-hiding commitments. Here we follow the “direct route” discussed in the introduction (rather than the “inaccessible entropy route”).

For simplicity, we focus on bit commitment schemes (in which messages are just single bits). As usual, full-fledged commitment schemes (for long messages) can be obtained by committing bit-by-bit.

**Definition 4.1** (Bit Commitment Scheme). A bit commitment scheme is an interactive protocol between two polynomial-time parties — the sender S and the receiver R — that satisfies the following properties.

1. The protocol proceeds in two stages: the commit stage and the reveal stage.

2. At the start of the commit stage both parties get a security parameter $1^n$ as a common input and the sender S also gets a private input $b \in \{0,1\}$. At the end of the commit stage the parties have a shared output $c$, which is called the commitment, and the sender S has an additional private output $d$, which is called the decommitment.

3. In the reveal stage, the sender S sends $(b,d)$ to the receiver R. The receiver R accepts or rejects based on $c$, $d$ and $b$. If both parties follow the protocol, then the receiver R always accepts.

In this section we focus on commitment schemes that are statistically-hiding and computationally-binding.

**Definition 4.2** (Statistically Hiding Bit Commitment). A bit commitment scheme $(S,R)$ is statistically-hiding if for every cheating receiver $R^*$ it holds that

$$SD((S(0),R^*)(1^n),(S(1),R^*)(1^n)) = \text{negl}(n),$$

where $(S(b),R^*)(1^n)$ denotes the transcript of the interaction between $R^*$ and $S(b)$ in the commit stage.

**Definition 4.3** (Computationally Binding Bit Commitment). A bit commitment scheme $(S,R)$ is computationally-binding if for every family of polynomial-size circuits sender $S^* = (S^*_n)_{n \in \mathbb{N}}$ it holds that $S^*$ wins in the following game with only with $\text{negl}(n)$ probability:

1. The cheating sender $S^*_n$ interacts with the honest receiver $R(1^n)$ in the commit stage obtaining a commitment $c$.

2. Then, $S^*_n$ outputs two pairs $(0,d_0)$ and $(1,d_1)$. The cheating sender $S^*$ wins if the honest receiver $R$ accepts both $(c,0,d_0)$ and $(c,1,d_1)$.

We are now ready to state the main result of this section. A round of a commitment scheme is a pair of messages, the first sent from the receiver to the sender, and the second the other way.

**Theorem 4.4** (MCRH $\Rightarrow$ Constant-Round Statistically-Hiding Commitments). Let $t = t(n) \in \mathbb{N}$ be a polynomial computable in $\text{poly}(n)$ time. Assume that there exists a $(s,t)$-MCRH for $s \geq \log(t)$, then there exists a three-round statistically-hiding computationally-binding commitment scheme.
As we already mentioned in Section 1, constructions of statistically-hiding computationally-binding commitment schemes are known assuming only the minimal assumption that one-way functions exist. Those constructions, however, have a polynomial number of rounds (and this is inherent for black-box constructions [HHRS15]). Theorem 4.4, on the other hand, yields a commitment scheme with only a constant (i.e., three) number of rounds.

The rest of this section is dedicated to proving Theorem 4.4.

4.1 Proving Theorem 4.4

The proof follows the outline detailed in Section 1.3.2.

Let $\text{Gen}$ be the generating algorithm that defines an $(s, t)$-MCRH for $s \geq \log(t)$, assumed to exist in the theorem’s statement. Since $s$ must be an integer, we can assume without loss of generality that the function defined by $\text{Gen}$ is $(\lceil \log(t) \rceil, t)$-MCRH (we can always pad the output of the function without making it easier to find collisions). The commitment scheme is defined in Fig. 2. The proof follows from the next two lemmas.

Lemma 4.5 (Computationally Binding). The commitment scheme $(S, R)$ in Fig. 2 is computationally binding.

Lemma 4.6 (Statistically Hiding). The commitment scheme $(S, R)$ in Fig. 2 is statistically hiding.

The proof of Lemma 4.5 is given in Section 4.1.1 and the proof of Lemma 4.6 is given in Section 4.1.2.

4.1.1 Analyzing Binding — Proving Lemma 4.5

Assume toward a contradiction that the scheme is not computationally binding. That is, there exists a polynomial-size family of circuits $S^* = (S_n^*)_{n \in \mathbb{N}}$, an infinite index set $\mathcal{I} \subseteq \mathbb{N}$ and a polynomial $q$ such that for every $n \in \mathcal{I}$ the following events occur with probability at least $1/q(n)$: (1) the cheating sender $S_n^*$ interacts with the honest receiver $R(1^n)$ in the commit stage of the protocol and the parties obtain a commitment $c = (h, y = (y_1, \ldots, y_k), f, z_1, g, z_2, r, \sigma)$; then, (2) $S_n^*$ outputs valid decommitments to two distinct values $(0, x = (x_1, \ldots, x_k))$ and $(1, x' = (x'_1, \ldots, x'_k))$ such that

$$\forall i \in [k]: h(x_i) = h(x'_i) = y_i$$
$$f(x) = f(x') = z_1 \quad \text{and} \quad g(x) = g(x') = z_2$$
$$\langle r, x \rangle \oplus 0 = \sigma \quad \text{and} \quad \langle r, x' \rangle \oplus 1 = \sigma. \quad (3)$$

Whenever the above conditions are met, we say that $S^*$ wins. We use $S^*$ to find a $t$-way collision in $H$, thereby deriving a contradiction.

Let $\tau$ be a sequence of random coins used by $S^*$ during its interaction with $R$.\(^\dagger\) Observe that $y$, the first message sent by $S^*$, is a deterministic function of $\tau$ and $h$, where $h$ is the first message sent by $R$ (i.e., a description of an MCRH). Similarly, $z_1$, the second message sent by $S^*$, is a deterministic function of $\tau$, $h$ and $f$, where $f$ is the second message sent by $R$. Finally, $r$, $\sigma$, $x$ and

\(^\dagger\)Since $S^*$ is a non-uniform adversary, we could have assumed without loss of generality that it is deterministic. We refrain from doing so to highlight that our reduction is uniform.
The Commitment Scheme (S, R)

S’s Input: security parameter $1^n$ and a bit $b \in \{0, 1\}$.
R’s Input: security parameter $1^n$.

Algorithm Gen: polynomial-time algorithm that on input $1^n$ returns a circuit computing a $(\lceil \log(t(n)) \rceil, t(n))$-MCRH $h: \{0, 1\}^n \rightarrow \{0, 1\}^{n-\lceil \log(t(n)) \rceil}$

The commit stage:
1. Both parties set $t = t(n)$ and $k = n \cdot t$.
2. R samples $h \leftarrow \text{Gen}(1^n)$ and sends $h$ to S.
3. S samples $x = (x_1, \ldots, x_k) \leftarrow \{0, 1\}^{n \cdot k}$, computes $y = (y_1, \ldots, y_k)$, where $y_i = h(x_i)$ for all $i \in [k]$, and sends $y$ to R.
4. R samples $f \leftarrow \mathcal{F}_{n,k,\lceil k \log(t-1) \rceil}$ and sends $f$ to S.
5. S sends $z_1 = f(x)$ to R.
6. R samples $g \leftarrow \mathcal{F}_{n,k,\lceil 2 \log(k) + 2 \log \log(t-1) + \log^2(n) \rceil}$ and sends $g$ to S.
7. S sends $z_2 = g(x)$ to R.
8. S samples $r \leftarrow \{0, 1\}^{n \cdot k}$ and computes $\sigma = \langle r, x \rangle \oplus b$ and sends $(r, \sigma)$ to R.
9. The commitment is defined as $c = (h, y, f, z_1, g, z_2, r, \sigma)$ and the decommitment is defined as $d = x$.

The reveal stage:
1. S sends $(b, x)$ to R.
2. R accepts if $h(x_i) = y_i$ for every $i \in [k]$, $f(x) = z_1$, $g(x) = z_2$ and $\langle r, x \rangle \oplus b = \sigma$.

*Recall that $\mathcal{F}_{n,m}^{(k)}$ is a family of $k$-wise-independent hash functions from $\{0, 1\}^n$ to $\{0, 1\}^m$ (see Section 2.1).*

Figure 2: Statistically Hiding Commitment
CollFinder, on input \((1^n, h)\):

1. Set \(t = t(n)\), \(k = n \cdot t\) and \(q = q(n)\)
2. Sample at random coins\(^a\) for \(S_n\), denoted by \(\tau\)
3. Emulate\(^b\) \(S_n(h; \tau)\) to obtain \(y = (y_1, \ldots, y_k)\)
4. For every \(i \in [k]\), set \(S_i = \emptyset\)
5. Repeat for \(4 \cdot q^2 \cdot n \cdot (t - 1) \cdot k^2\) times:
   a. Sample \(f \leftarrow \mathcal{F}_{n,k,[k\log(t-1)]}\)
   b. Emulate \(S_n(f; \tau)\) to obtain \(z_1\)
   c. Sample \(g \leftarrow \mathcal{F}_{n,k,[2\log(k)+2\log(t-1)+\log^2(n)]}\)
   d. Emulate \(S_n(g; \tau)\) to obtain \(r, \sigma, x = (x_1, \ldots, x_k)\) and \(x' = (x_1', \ldots, x_k')\)
   e. If \(S^*\) wins,\(^c\) then for every \(i\) update \(S_i = S_i \cup \{x_i, x'_i\}\)
6. Output \(S_{\text{out}} = S_j\) such that \(j = \arg\max_i\{|S_i|\}\)

\(^a\)Since we consider a non-uniform adversary \(S^*\), we could have simply fixed its random coins. However, we avoid doing so to highlight that the reduction is uniform.

\(^b\)By \(\mathcal{A}(\cdot; \tau)\) we mean that \(\mathcal{A}\) is run when its coins are set to \(\tau\).

\(^c\)Namely, if the conditions in Eq. (3) are satisfied, or equivalently if \((f, g) \in \mathcal{W}_{h, \tau}\).

Figure 3: Algorithm to find \(t\)-collision in \(\mathcal{H}\)

\(x',\) the values sent in the third message of \(S^*\), are all deterministic functions of \(\tau, h, f\) and \(g\), where \(g\) is the third message sent by \(R\). Hence, for any \(\tau\) and \(h\) we can define a set

\[
\mathcal{W}_{\tau, h} = \left\{ (f, g) : (h, y, f, g, r, \sigma, x, x') \text{ satisfy the conditions in Eq. (3)} \right\}.
\]

That is, \(\mathcal{W}_{\tau, h}\) contains all many-wise independent hash functions \(f\) and \(g\) that lead the adversary to successfully break the binding property of the commitment scheme (with respect to the fixed \(\tau\) and \(h\)).

We can now describe the algorithm for finding \(t\)-way collision in \(\mathcal{H}\). The (non-uniform) algorithm \(\text{CollFinder} = (\text{CollFinder}_n)_{n \in \mathbb{N}}\) is defined in Fig. 3.

It is easy to verify that \(\text{CollFinder}_n\) is of polynomial size.\(^{18}\) In the rest of the proof we show that \(\text{CollFinder}\) finds \(t\)-way collision in \(\mathcal{H}\) with probability roughly \(1/q(n)\), which is a contradiction to the multi-collision resistance of \(\mathcal{H}\).

Intuitively, the sets \(S_i\) store collisions of \(h\). The choice of \(f\) and \(g\) guarantee that, with probability at least \(1/\text{poly}(n)\) and as long as \(|S_i| < t\) for every \(i\), in every iteration the main loop of \(\text{CollFinder}\) in which \(S^*\) wins, at least one of the \(S_i\) increases. Iterating the loop for sufficiently many times guarantees that with probability at least \(1/\text{poly}(n)\), one of the \(S_i\)'s contains at least \(t\) values (i.e., a \(t\)-way collision) at the end of the loop.

Formally, fix some large enough \(n \in \mathcal{I}\) and remove it from notation. Observe that \(S_{\text{out}}\), the set of alleged collisions returned by \(\text{CollFinder}\), is updated only when \(S^*\) wins. Thus, it holds that \(h(x) = h(x')\) for every \(x, x' \in S_{\text{out}}\). Let \(L\) be random variable equal to the size of \(S_{\text{out}}\) in a random execution of \(\text{CollFinder}(1^n, h)\), for \(h \leftarrow \text{Gen}(1^n)\). Hence, our goal is to show that

\[
\Pr[L \geq t] \geq \Omega(1/q).
\]  

\(^{18}\)We assume, without loss of generality, that \(q(n)\) can be computed in time \(\text{poly}(n)\) (otherwise, take \(q' > q\) that is efficiently computed)
Our first step is to analyze how the choice of \((\tau, h)\) affects the success probability of \text{CollFinder}. Let \(b \in \{0, 1\}\) and let \((T, H, F, G)\) be (jointly distributed) random variables induced by the values of \((\tau, h, f, g)\) in a random execution of \((S^*(b), R)\) where \(\tau\) are the random coins used by \(S^*\) (note that these random variables are identically distributed if \(b = 0\) or \(b = 1\)). Note that \((T, H)\) are independent of \((F, G)\), the random variable \(H\) is distributed as the output of \text{Gen}(1^n)\) and \(T\) is distributed as the value of \(\tau\) in Step 2 in a random execution of \text{CollFinder}(1^n, H). Let

\[
\mathcal{W} = \left\{ (\tau, h) : \Pr[(F, G) \in \mathcal{W}_{\tau, h}] \geq \frac{1}{q^2} \right\}.
\]

We make use of the next claim.

**Claim 4.6.1.** It holds that \(\Pr[(T, H) \in \mathcal{W}] \geq 1/(2q)\).

**Proof.** Let \(P_{\tau, h} = \Pr[(F, G) \in \mathcal{W}_{\tau, h}]\). We can lower bound the expectation of the random variable \(P_{T, H}\) as follows:

\[
E[P_{T, H}] = \Pr[(F, G) \in \mathcal{W}_{T, H}] = \Pr[S^* \text{ wins}] \geq \frac{1}{q}.
\]

Using elementary probability, and the fact that \(P_{T, H}\) takes values in \([0, 1]\), we have that:

\[
\frac{1}{q} \leq E[P_{T, H}] \leq \frac{1}{q^2} \cdot \Pr[P_{T, H} < \frac{1}{q^2}] + 1 \cdot \Pr[P_{T, H} \geq \frac{1}{q^2}] \leq \frac{1}{q^2} + \Pr[P_{T, H} \geq \frac{1}{q^2}]
\]

and so \(\Pr[P_{T, H} \geq \frac{1}{q^2}] \geq \frac{1}{q} - \frac{1}{q^2} \geq \frac{1}{2q}\).

For \(\tau, h\), let \(L_{\tau, h}\) denote the random variable distributed as \(L\) conditioned on \((T, H) = (\tau, h)\). Using Claim 4.6.1, we have that

\[
\Pr[L \geq t] = \sum_{(\tau, h) \in (T, H)} E_{(\tau, h) \sim (T, H)} \Pr[L_{\tau, h} \geq t]
\]

\[
\geq \Pr[(T, H) \in \mathcal{W}] \cdot \sum_{(\tau, h) \in (T, H)} E_{(\tau, h) \sim (T, H)} \Pr[L_{\tau, h} \geq t \mid (\tau, h) \in \mathcal{W}]\]

\[
\geq \frac{1}{q} \cdot \sum_{(\tau, h) \in (T, H)} \Pr[L_{\tau, h} \geq t \mid (\tau, h) \in \mathcal{W}]\]

In the rest of the proof we show that for every fixed \((\tau, h) \in \mathcal{W}\), it holds that

\[
\Pr[L_{\tau, h} \geq t] \geq 1 - \text{negl}(n).
\]

At this point it might be helpful to provide an explanation of our approach in the rest of the proof. Our goal is to show that with high probability \text{CollFinder} finds \(t\)-way collision, or equivalently that at the end of the loop in Step 5 at least one of the sets \(S_1, \ldots, S_k\) contains at least \(t\) elements. By definition, these sets are updated only when \(S^*\) wins in some iteration \(j\) of the loop. However, even if \(S^*\) wins in the \(j\)'th iteration it does not necessarily mean that the size of one of the \(S_i\)'s increased, namely that there exists \(i \in [k]\) such that \(x_i \notin S_i\) or \(x_i' \notin S_i\). The latter condition is guaranteed to occur if some injective condition — denoted for now by \(\text{inj}^{(j)}\) — is met, where \(\text{inj}^{(j)}\) is defined over the choice of the functions \(f\) and \(g\) chosen in the \(j\)'th iteration and the current value of
the sets $S_1, \ldots, S_k$ (i.e., the value at the beginning of the $j$'th iteration). If $\text{inj}^{(j)}$ is met for enough iterations (roughly $t \cdot k$), one of the sets must contain at least $t$ elements.

Ideally, we would like to argue that $\text{inj}^{(j)}$ occurs in many iterations since in every iteration $f$ and $g$ are chosen independently from many-wise independent hash families. However, arguing this turns out not to be straightforward. The reason being the dependency between $\text{inj}^{(j)}$ and $\text{inj}^{(j')}$, for $j' < j$. Indeed, $\text{inj}^{(j)}$ depends on the value of the sets $S_1, \ldots, S_k$ at the beginning of the $j$'th iteration, and the value of these sets depends on whether previous injective conditions were met.

To circumvent this issue we take a different approach — instead of analyzing the dynamic updates of the sets $S_1, \ldots, S_k$, we fix in advanced sets $S'_1, \ldots, S'_k$, all of which contain at most $t - 1$ elements. We show that only with very small probability the sets $S_1, \ldots, S_k$ are equal to $S'_1, \ldots, S'_k$ at the end of CollFinder's run. To do so, we redefine $\text{inj}^{(j)}$ to depend on the functions $f$ and $g$ that are chosen in the $j$'th iteration and the fixed sets $S'_1, \ldots, S'_k$. Having done that, $\text{inj}^{(j)}$ and $\text{inj}^{(j')}$ are now indeed independent, and a straightforward analysis can be applied. To complete the argument we must show the above for any possible choice of $S'_1, \ldots, S'_k$. Since $|S'_1| < t$, there are (relatively) a small number of possible choices for $S'_1, \ldots, S'_k$, and we can apply a union bound over all of them.

Going back to the formal proof, fix $(\tau, h) \in W$ and let $A_1, \ldots, A_k$ be random variables induced by the values of the sets $S_1, \ldots, S_k$ at the end of a random execution of CollFinder, conditioned on $(T, H) = (\tau, h)$. It holds that

$$\Pr[L_{\tau, h} < t] = \Pr[A_i < t - 1 \text{ for every } i \in [k]] \leq \sum_{S'_1, \ldots, S'_k \subseteq \{0,1\}^n \text{ for every } i \in [k]} \Pr[A_i = S'_i, \text{ for every } i \in [k]],$$

where the last inequality follows from the union bound. Fix $S'_1, \ldots, S'_k \subseteq \{0,1\}^n$ with $|S'_i| \leq t - 1$ for every $i \in [k]$. For a function $f: \{0,1\}^n \rightarrow \{0,1\}^{[k \cdot \log(t - 1)]}$ and value $z \in \{0,1\}^{[k \cdot \log(t - 1)]}$, let $S_{f,z} = f^{-1}(z) \cap (S'_1 \times \cdots \times S'_k)$. The crux of the proof is the next two claims.

**Claim 4.6.2.** If $(h, y, f, z_1, g, z_2, r, \sigma, x, x')$ satisfy the conditions in Eq. (3) and $g$ is injective over $S_{f,z_1}$, then there exists $i \in [k]$ such that $x_i \notin S'_i$ or $x'_i \notin S'_i$.

**Proof.** First, note that since the conditions in Eq. (3) are satisfied, it holds that $\langle r, x \rangle \oplus 0 = \sigma$ and $\langle r, x' \rangle \oplus 1 = \sigma$, and thus $x \neq x'$.

Assume toward a contradiction that $x_i \in S'_i$ and $x'_i \in S'_i$ for every $i \in [k]$. It follows that $x, x' \in S'_1 \times \cdots \times S'_k$. Since the conditions in Eq. (3) are satisfied it holds that $f(x) = f(x') = z_1$, and thus $x, x' \in S_{f,z_1}$. Using once more that the conditions in Eq. (3) are satisfied it holds that $g(x) = g(x')$, a contradiction to the assumption that $g$ is injective over $S_{f,z_1}$. \hfill \Box

Recall that $z_1$, the sender’s message in the second round of the commitment protocol, is a deterministic function of $\tau$, $h$ and $f$, and since $\tau$ and $h$ are fixed, $z_1$ is a deterministic function of $f$, i.e., $z_1 = z_1(f)$. For $(f, g)$, let $\text{inj}(f, g) = 1$ if $g$ is injective over the set $S_{f,z_1}(f)$.

**Claim 4.6.3.** It holds that

$$\Pr[\text{inj}(F, G) = 0] \leq \frac{1}{2q^2}.$$
Proof. For \( f \in \text{Supp}(F) \), let \( B_f = \left| S_{f,z_1(f)} \right| \). First, we show that with high probability \( B_F \) is small. Indeed, since \( |S'_i| \leq (t - 1) \) for every \( i \in [k] \), it follows that \( |S'_1 \times \cdots \times S'_k| \leq (t - 1)^k \). Moreover, since \( F \) is chosen from the family \( \mathcal{F}_{n,k,[k\cdot \log(t-1)]} \), Fact 2.3 (about the load balancing of many-wise independent functions) yields that

\[
\Pr[B_F \geq 2 \cdot [k \cdot \log(t - 1)]] \leq \Pr[\exists z : |S_{F,z}| \geq 2 \cdot [k \cdot \log(t - 1)]]
\leq 2^{-2 \cdot [k \cdot \log(t - 1)] + [k \cdot \log(t - 1)]} = 2^{-[n \cdot t \cdot \log(t - 1)]}.
\]

Second, we show that if \( B_F \) is small, then \( \text{inj}(F,G) = 1 \) with high probability. Recall that in the protocol \((S^*, R)\), the function \( G \) is chosen (independently from everything else) from the pairwise independent family \( \mathcal{F}_{n,k,[2 \log(k) + 2 \log \log(t - 1) + \log^2(n)]} \) after \( z_1(F) \) (and \( S_{F,z_1(F)} \)) is determined. Thus, we can use the pairwise independence of \( G \) to complete the proof. Fix \( f \in \text{Supp}(F) \) with \( B_f < 2 \cdot [k \cdot \log(t - 1)] \). It holds that

\[
\Pr[\text{inj}(F,G) = 0 \mid F = f] = \Pr[\exists x \neq x' \in S_{f,z_1(f)} : G(x) = G(x')]
\leq \sum_{x \neq x' \in S_{f,z_1(f)}} \Pr[G(x) = G(x')]
\leq \frac{(2(k \cdot \log(t - 1) + 1))^2}{(k^2 \cdot \log^2(t - 1) \cdot 2\log^2(n))}
\leq 10 \cdot 2^{-\log^2(n)}.
\]

Finally, combining the above we have that

\[
\Pr[\text{inj}(F,G) = 0] \leq \Pr[B_F \geq 2 \cdot [k \cdot \log(t - 1)]] + \Pr[\text{inj}(F,G) = 0 \mid B_F < 2 \cdot [k \cdot \log(t - 1)]]
\leq 2^{-[n \cdot t \cdot \log(t - 1)]} + 10 \cdot 2^{-\log^2(n)}
\leq \frac{1}{2q^2},
\]

where the last inequality holds for large enough \( n \) and since \( q \in \text{poly}(n) \).

Using the above claims, we can proceed to complete the proof. For \( j \in [4 \cdot q^2 \cdot n \cdot (t - 1) \cdot k^2] \) let \( F^{(j)} \) and \( G^{(j)} \) be random variables induced by the values of \( f \) and \( g \) in \( j \)'th iteration of the loop in Step 5 in a random execution of CollFinder, conditioned on \((T, H) = (\tau, h)\). Claim 4.6.2 implies that if \( \text{inj}(F^{(j^*)}, G^{(j^*)}) = 1 \) and \((F^{(j^*)}, G^{(j^*)}) \in \mathcal{W}_{\tau, h} \) for some \( j^* \), then the random variables
A_1, \ldots, A_k cannot take the values of the sets S'_1, \ldots, S'_k. It follows that
\[
\Pr[A_i = S'_i, \text{ for every } i \in [k]] \leq \Pr[\forall j \in [4 \cdot q^2 \cdot n \cdot (t-1) \cdot k^2], \text{ inj}(F^{(j)}, G^{(j)}) = 0 \vee (F^{(j)}, G^{(j)}) \notin W_{\tau,h}] 
\]
\[
= \prod_{j=1}^{4 \cdot q^2 \cdot n \cdot (t-1) \cdot k^2} \Pr[\text{ inj}(F^{(j)}, G^{(j)}) = 0 \vee (F^{(j)}, G^{(j)}) \notin W_{\tau,h}] 
\]
\[
\leq \prod_{j=1}^{4 \cdot q^2 \cdot n \cdot (t-1) \cdot k^2} \left( \Pr[\text{ inj}(F^{(j)}, G^{(j)}) = 0] + \Pr[(F^{(j)}, G^{(j)}) \notin W_{\tau,h}] \right) 
\]
\[
\leq \prod_{j=1}^{4 \cdot q^2 \cdot n \cdot (t-1) \cdot k^2} \left( \frac{1}{2q^2} + 1 - \frac{1}{q^2} \right) 
\]
\[
\leq \left( 1 - \frac{1}{2q^2} \right)^{4 \cdot q^2 \cdot n \cdot (t-1) \cdot k^2} 
\]
\[
\leq e^{-2 \cdot n \cdot (t-1) \cdot k^2}, 
\]
where the first equality follows since (F^{(j)}, G^{(j)})'s are independent, the third inequality follows from Claim 4.6.3, since (\tau, h) \in W and since (F^{(j)}, G^{(j)}) are identically distributed as (F, G), and the last inequality follows since \(1 - x \leq e^{-x}\) for any \(x \in (0, 1)\).

Finally, we bound the number of different sets S'_1, \ldots, S'_k with \(|S'_i| \leq t - 1\). For every S'_i, there are \[
\sum_{s=1}^{t-1} \binom{2^{n-k}}{s} \leq (t-1) \cdot 2^{n-k(t-1)} \leq 2^{2n-(t-1)k}
\]
different possibilities, where the first inequality follows from the bound \(\sum_{i=0}^{k} \binom{n}{i} \leq k \cdot n^k\). Hence, there are at most \(\binom{2^{2n-(t-1)k}}{k} = 2^{2n-(t-1)k^2}\) different possibilities for S'_1, \ldots, S'_k.

Combining Eqs. (7) and (8) yields that
\[
\Pr[L_{\tau,h} < t] \leq 2^{2n-(t-1)k^2} \cdot e^{-2n-(t-1)k^2} = \text{negl}(n).
\]
Hence, Eq. (6) holds, and the proof of Lemma 4.5 is complete.

### 4.1.2 Analyzing Hiding — Proving Lemma 4.6

The crux of proving that the scheme is statistically-hiding is the following observation: If a function d is shrinking and X is a random input for it, then the random variable \((X \mid d(X))\) has (some form of) conditional min-entropy. Therefore, the receiver — who sees only \(d(X)\) — cannot completely recover \(X\). The actual notion of entropy we use is that of average min-entropy.

The notion of average min-entropy was defined by Dodis et al. [DORS08] as follows.

**Definition 4.7 (Average Min-Entropy [DORS08]).** Let \(X, Y\) be jointly distributed random variables. The average min-entropy of \(X\) given \(Y\) is defined by
\[
\bar{H}_{\text{min}}(X \mid Y) := -\log \left( \mathbb{E}_{Y \rightarrow Y} \left[ \max_x \Pr[X = x \mid Y = y] \right] \right).
\]
We can show that if \( d \) is shrinking, then the average min-entropy of \( (X \mid d(X)) \) is high.

**Claim 4.7.1.** Let \( d : \{0,1\}^n \rightarrow \{0,1\}^{n-m} \), let \( X \) be a random variable uniformly distributed over \( \{0,1\}^n \), and let \( Y = d(X) \). Then, \( \bar{H}_{\text{min}}(X|Y) \geq m \).

**Proof.** For \( y \in \{0,1\}^{n-m} \), let \( d^{-1}(y) = \{ x \in \{0,1\}^n : d(x) = y \} \). Fix \( y \in \text{Im}(d) \). For \( x \in d^{-1}(y) \), it holds that \( \Pr[X = x \mid Y = y] = 1/|d^{-1}(y)| \), while for \( x \notin d^{-1}(y) \), it holds that \( \Pr[X = x \mid Y = y] = 0 \). Thus, \( \max_x \Pr[X = x \mid Y = y] = 1/|d^{-1}(y)| \). Moreover, it holds that \( \Pr[Y = y] = |d^{-1}(y)|/2^n \). Finally, for every \( y \notin \text{Im}(d) \), it holds that \( \Pr[Y = y] = 0 \). Hence,

\[
\bar{H}_{\text{min}}(X|Y) = - \log \left( \mathbb{E}_{y \sim Y} \left[ \max_x \Pr[X = x \mid Y = y] \right] \right)
\]
\[
= - \log \left( \sum_{y \in \text{Im}(d)} \frac{|d^{-1}(y)|}{2^n} \cdot \frac{1}{|d^{-1}(y)|} \right)
\]
\[
= \log \left( \frac{2^n}{|\text{Im}(d)|} \right)
\]
\[
\geq m.
\]

\( \Box \)

Showing that a random variable has average min-entropy is useful since the Leftover Hash Lemma can be generalized to sources having high average min-entropy. We first recall the definition of universal hash functions and then state the (generalized) Leftover Hash Lemma for high average min-entropy sources.

**Definition 4.8 (Universal Hash Function).** A family of functions \( \mathcal{F} = \{ f : \{0,1\}^n \rightarrow \{0,1\}^m \} \) is Universal if for every \( x_1 \neq x_2 \in \{0,1\}^n \), it holds that

\[
\Pr_{f \sim \mathcal{F}}[f(x_1) = f(x_2)] = \frac{1}{2^m}.
\]

**Lemma 4.9 (Generalized Leftover Hash Lemma [DORS08, Lemma 2.4]).** Let \( \mathcal{F} = \{ f : \{0,1\}^n \rightarrow \{0,1\}^m \} \) be a family of universal hash functions. Then, for any random variables \( X \) and \( Y \) and the random variable \( F \leftarrow \mathcal{F} \), it holds that

\[
\text{SD} \left( (F(X), F(Y)), (U_m, F(Y)) \right) \leq \frac{1}{2} \cdot \sqrt{2^{-H_{\text{min}}(X|Y)} \cdot 2^m},
\]

where \( U_m \) is distributed uniformly over \( \{0,1\}^m \).

We are now finally ready to prove that the scheme is statistically-hiding.

**Proof of Lemma 4.6.** Let \( R^* \) be any (possibly unbounded) algorithm. Fix large enough \( n \in \mathbb{N} \) and remove it from notation when convenient. Let \( (H^*, X = (X_1, \ldots, X_k), F^*, G^*, r) \) be (jointly distributed) random variables induced by the values of \( (h^*, x = (x_1, \ldots, x_k), f^*, g^*, r) \) in a random execution of \( (S(b), R^*) \), for an arbitrary \( b \in \{0,1\} \).

The transcript of the interaction between \( S(b) \) and \( R^* \) for any \( b \in \{0,1\} \) is thus

\[
(S(b), R^*) \equiv (H^*, H^*(X_1), \ldots, H^*(X_k), F^*, F^*(X), G^*, G^*(X), r, \langle r, X \rangle \oplus b).
\]

\[19\text{Note that these random variables are identically distributed if } b = 0 \text{ or } b = 1.\]
Note that \((H^*, F^*, G^*)\) can be viewed as a description of a function \(Q^*\) mapping \(n \cdot k\) bits to \(n \cdot k - m\) bits for \(m := k \cdot \lceil \log t \rceil - \lceil k \cdot \log(t-1) \rceil - \left[2 \log(k) + 2 \log \log(t-1) + \log^2(n)\right]\) bits. Namely, \(Q^*(X) = (H^*(X_1), \ldots, H^*(X_k), F^*(X), G^*(X))\). We can thus write
\[
(S(b), R^*) \equiv (Q^*, Q^*(X), r, \langle r, X \rangle \oplus b).
\]

Fix \(b \in \{0, 1\}\) and let \(U \leftarrow \{0, 1\}\) be a uniform bit. It holds that
\[
\SD \left( (Q^*, Q^*(X), r, \langle r, X \rangle \oplus b), (Q^*, Q^*(X), r, U) \right) = \E_{q^* \leftarrow Q^*} \left[ \SD \left( (q^*(X), r, \langle r, X \rangle \oplus b), (q^*(X), r, U \oplus b) \right) \right] \leq \frac{1}{2} \cdot \sqrt{2^{-\min_q(\|q^*(X)\| \cdot 2)}} \leq \frac{1}{2} \cdot 2^{-(m-1)/2},
\]
where the equality follows since \(r\) and \(X\) are independent of \(Q^*\), the first inequality follows from Lemma 4.9 (Generalized Leftover Hash Lemma) and since inner product is a universal hash function, and the second inequality follows from Claim 4.7.1.

Finally, by the setting of parameters and for large enough \(n\) it holds that
\[
m = k \cdot \lceil \log t \rceil - \lceil k \cdot \log(t-1) \rceil - \left[2 \log(k) + 2 \log \log(t-1) + \log^2(n)\right] \geq \frac{1}{t-1} - 2 \log(k) - 2 \log \log(t-1) - \log^2(n) - 2 \geq \frac{1}{t-1} - 2 \log(n \cdot t) - 2 \log \log(t-1) - \log^2(n) - 2 \geq \log^3(n).
\]

Putting it all together, it holds that
\[
\SD((S(0), R^*), (S(1), R^*)) = \SD \left( (Q^*, Q^*(X), R, \langle R, X \rangle \oplus 0), (Q^*, Q^*(X), R, \langle R, X \rangle \oplus 1) \right) \leq \sum_{b \in \{0, 1\}} \SD \left( (Q^*, Q^*(X), R, \langle R, X \rangle \oplus b), (Q^*, Q^*(X), R, U) \right) \leq 2^{-(m-1)/2} \leq 2^{-(\log^3(n)-1)/2} = \negl(n),
\]
where the first inequality follows from the triangle inequality for statistical distance, the second inequality follows from Eq. (9) and the last inequality follows from Eq. (10).

\section{Black-Box Separation}

In this section, we formally state and prove a black-box separation between MCRH and one-way permutations. This separation is a straightforward corollary of our black-box construction of
constant-round statistically-hiding commitments from MCRH (Theorem 4.4) and the known black-box separation between constant-round statistically-hiding commitment schemes and one-way permutations by Haitner, Hoch, Reingold and Segev [HHRS15]. As mentioned in the introduction, the result of this section can be viewed as an extension of Simon’s [Sim98] blackbox separation of CRH from one-way permutations.

We start by defining one-way permutations followed by the notion of fully-black-box construction of MCRH from one-way permutations.

**Definition 5.1 (One-way Permutations).** A family $F = \{F_n\}_{n \in \mathbb{N}}$ of polynomial time computable functions is called a one-way permutation if the following hold:
1. $f_n : \{0,1\}^n \rightarrow \{0,1\}^n$ is a permutation for all $f_n \in F_n$.
2. For every probabilistic polynomial time algorithm $A$, and for sufficiently large $n$, it holds that,

$$\Pr[A(f^1, y) = f^{-1}(y)] \leq \text{negl}(n),$$

where $\text{negl}(\cdot)$ is some negligible function and the probability is over $y \leftarrow \{0,1\}^n$ and the randomness of $A$.

**Definition 5.2.** A fully black-box construction of a $(s(n), t(n))$-multi-collision resistant function family, where $s(n) \geq \log t(n)$, from a family of $\tau(n)$-hard one-way permutations is a pair of probabilistic polynomial-time oracle-aided algorithms $(Gen, M)$ for which the following hold:

- **Black-Box Construction:** Given any family of permutations $f = \{f_n : \{0,1\}^n \rightarrow \{0,1\}^n\}_{n \in \mathbb{N}}$, the algorithm $Gen^f(1^n)$ outputs the description of an oracle-aided circuit $C^f : \{0,1\}^n \rightarrow \{0,1\}^{n-s(n)}$.

- **Black-Box Proof of Multi-Collision Resistance:** For every family $f = \{f_n : \{0,1\}^n \rightarrow \{0,1\}^n\}_{n \in \mathbb{N}}$ of permutations and for every probabilistic polynomial-time algorithm $A$, if $A$ with oracle access to $f$ breaks the $(s(n), t(n))$-multi-collision resistance of $Gen^f$ then,

$$\Pr[M^f_A(y) = f^{-1}(y)] \geq \frac{1}{\tau(n)}$$

for infinitely many values of $n$, where $M$ runs in time $\tau(n)$ and the probability is over all possible choices of $f$ and $y \in \{0,1\}^n$ and the randomness of $M$.

We say that a fully black-box construction $(Gen, M)$ is $\ell(n)$-security-parameter-expanding if for every adversary $A$ from above, the reduction $M$ on security parameter $1^n$ invokes $A$ on security parameters which are at most $1^{\ell(n)}$.

We will rule out fully-black-box constructions of $(s, t)$-MCRHs from one-way permutations for all $s \geq \log t$. In contrast, note that $(\log(t-1), t)$-MCRHs exist trivially (and unconditionally) for all values of $t$.\(^{20}\)

**Theorem 5.3 (Restatement of Corollary 3).** Let $(Gen, M)$ be an $\ell(n)$-security-parameter-expanding fully-black-box construction of $(s, t)$-MCRH from a family of $\tau(n)$-hard one-way permutations $F$, where $t = t(n) \in \mathbb{N}$ is a polynomial computable in $\text{poly}(n)$ time and $s(n) \geq \log(t(n))$, then

$$\tau(\ell(n)) = 2^{\Omega(n)}.$$  

\(^{20}\)Consider a $(t-1)$-regular function $f : \{0,1\}^n \rightarrow \{0,1\}^{n-\log(t-1)}$. For such a function $t$-way collisions simply do not exist.
Theorem 5.3 shows that there does not exist a fully black-box construction of MCRH from polynomially-hard one-way permutation. The proof of Theorem 5.3 relies on the black-box separation of constant-round statistically-hiding commitments from one-way permutations [HHRS15], stated now.

Definition 5.4. A fully black-box construction of a statistically-hiding commitment scheme from a family of $\tau(n)$-hard one-way permutations $F$, is a triple of probabilistic polynomial-time oracle-aided algorithms $(S, R, M)$ for which the following hold:

- **Correctness and Hiding:** The commitment scheme $(S^f, R^f)$ satisfies correctness (i.e., satisfies Definition 4.1) and statistical hiding (see Definition 4.2) for every $f \in F$.

- **Black-Box Proof of Binding:** For every family $f = \{f_n : \{0, 1\}^n \rightarrow \{0, 1\}^n\}_{n \in \mathbb{N}}$ of permutations and for every probabilistic polynomial-time algorithm $S^*$, such that $S^*$ breaks the binding of $(S^f, R^f)$, it holds that
  \[
  \Pr[M^f, S^*(y) = f^{-1}(y)] \geq \frac{1}{\tau(n)}
  \]
  for infinitely many values of $n$, where $M$ runs in time $\tau(n)$ and the probability is over all possible choices of $f$ and $y \in \{0, 1\}^n$ and the randomness of $M$.

We say that a fully black-box construction $(S, R, M)$ is $\ell(n)$-security-parameter-expanding if for every adversary $S^*$ from above, the reduction $M$ on security parameter $1^n$ invokes $S^*$ on security parameters which are at most $1^{\ell(n)}$.

Theorem 5.5 ([HHRS15, Theorem 6.3]). For every $\ell(n)$-security-parameter-expanding fully-black-box construction of a $d(n)$-round statistically hiding commitment scheme from an $\tau(n)$-hard family of one-way permutations, it holds that $d(\ell(n)) = \Omega\left(\frac{n}{\log \tau(n)}\right)$.

The proof of Theorem 5.3 is now a simple corollary of Theorem 5.5 together with the observation that our construction of a 3-round statistically-hiding commitment scheme from MCRH is fully black-box (Theorem 4.4).

Proof of Theorem 5.3. Let $(Gen, M)$ be an $\ell(n)$-security-parameter-expanding fully-black-box construction of $(s, t)$-MCRH from a family of $\tau(n)$-hard one-way permutations $F$, where $t = t(n) \in \mathbb{N}$ is a polynomial computable in $\text{poly}(n)$ time and $s(n) \geq \log t(n)$. Observe that the composition of our construction of a 3-round statistically hiding commitment from MCRH (Theorem 4.4) and the fully black-box construction $(Gen, M)$ yields an $\ell(n)$-security-parameter-expanding fully-black-box construction of a 3-round statistically hiding commitment from a $q(\ell(n)) \cdot \tau(\ell(n))$-hard family of one-way permutations for some polynomial $q$ determined by the proof of Theorem 4.4.

Theorem 5.5 now yields that,
\[
3 \geq c \cdot \frac{n}{\log q(\ell(n)) \cdot \tau(\ell(n))},
\]

This theorem can be strengthened by considering an additional parameter: the security reduction $M$’s running time. This allows us to rule out constructions relying on sub-exponential assumptions (c.f. [HHRS15, Footnote 21]). However, we do not consider this generalization here.
for some universal constant $c > 0$. Rearranging, we get

$$\tau(\ell(n)) \geq \frac{2^{c \cdot n}}{q(\ell(n))} = 2^{\Omega(n)},$$

where the second equality follows since $q$ and $\ell$ are polynomials.

\[ \square \]

\textbf{Acknowledgments}

We thank Vinod Vaikuntanathan for helpful discussions and for his support, and Oded Goldreich and Yuval Ishai for useful comments. We thank Nir Bitansky, Yael Kalai, Ilan Komargodski, Moni Naor, Omer Paneth and Eylon Yogev for helping us provide a good example of a $t$-way collision. We also thank Nir Bitansky and an anonymous reviewer for pointing out the connection to inaccessible entropy.
