Feasibly constructive proofs of succinct weak circuit lower bounds

Abstract

We ask for feasibly constructive proofs of known circuit lower bounds for explicit functions on bit strings of length $n$. In 1995 Razborov showed that many can be proved in Cook’s theory $PV_1$, a bounded arithmetic formalizing polynomial time reasoning. He formalized circuit lower bound statements for small $n$ of doubly logarithmic order. A more common formalization, considered in Krajíček’s 1995 textbook, assumes $n$ only of logarithmic order. It is open whether $PV_1$ proves known lower bounds in such succinct formalizations. We give such proofs in Jeřábek’s theory of approximate counting $APC_1$, an extension of $PV_1$ formalizing probabilistic polynomial time reasoning. Specifically, we prove in $APC_1$ lower bounds for the parity function and $AC^0$, for the mod $q$ counting function and $AC^0[p]$ (for some $n$ of intermediate order), and for the $k$-clique function and monotone circuits. We also formalize Razborov and Rudich’s natural proof barrier. Further, we ask for feasibly constructible propositional proofs of circuit lower bounds. We discuss two ways to succinctly express circuit lower bounds by propositional formulas of polynomial size $n^{O(1)}$ or at least much smaller than size $2^{O(n)}$ of the common formula based on the truth table of the function: one via feasible functions witnessing errors of circuits trying to compute some hard function, and one via the anticheckers of Lipton and Young 1994 or partial truth tables. Our $APC_1$ formalizations can be applied to derive a conditional upper bound on succinct propositional formulas obtained by witnessing extracted from the $APC_1$ proofs. Namely, we show these formulas have short Extended Frege $EF$ proofs from general circuit lower bounds expressed by the common “truth-table” formulas. We also show how to construct in quasipolynomial time propositional proofs of quasipolynomial size tautologies expressing $AC^0[p]$ quasipolynomial size lower bounds; these proofs are in Jeřábek’s proof system $WF$. The last result is proved by formalizing a variant of Razborov’s and Rudich’s naturalization of Smolensky’s proof for partial functions on the propositional level.

5 Questions 45
1 Introduction

It comes as no surprise when a complexity theorist, being concerned with the algorithmic
hardness of computational tasks, starts wondering whether the notorious conjectures in
the field are in some sense ‘hard’ to prove. Can one show first that existing proofs of partial
results are ‘simple’ in some sense and second that such ‘simple’ reasoning is insufficient
to settle the conjecture under consideration?

It is unclear whether there exists a good general notion of simplicity of proofs, already
Hilbert asked for it in his 24th problem [60]. From a complexity theoretic perspective,
however, one would naturally like to grade the complexity of proofs by the computational
complexity of the concepts and constructions appearing in it. This is the viewpoint of
In particular, the bounded arithmetic theory \( PV_1 \), going back to Cook [18], can be viewed
as being restricted to polynomial time computable concepts and constructions. In Cook’s
own words, “if one believes that all feasibly constructive arguments can be formalized in
\( PV_1 \), then it is worthwhile seeing which parts of mathematics can be so formalized.” [18,
p.96] As it turns out, a large part of contemporary complexity theory can be carried out
in \( PV_1 \) or slight extensions of it (see the table in Section 5).

An example of particular interest is the apparently difficult task to prove circuit lower
bounds for explicit functions. We consider three seminal results in the area:

(a) The Switching Lemma and a size lower bound for bounded depth circuits computing
the parity function [1, 23, 25].

(b) Razborov and Smolensky’s method of approximations by low degree polynomials
and a size lower bound for bounded depth circuits containing modulo \( p \) counting
gates computing the modulo \( q \) counting function [51, 57].

(c) Razborov’s method of approximations and a size lower bound for monotone circuits
deciding the clique problem [50].

We refer to [5] or [3] for surveys. We give proofs of (a)-(c) that are in a certain
sense feasibly constructive. This Introduction gives an informal description of and moti-
vation for our upper bounds and, moreover, aims to compactly survey the area, including
independence and lower bounds.

1.1 Circuit lower bounds in \( PV_1 \)

We continue Razborov’s search for the “right fragment capturing the kind of techniques
existing in Boolean complexity at present” [53, p.344]. He argued “that \( V_1 \) is exactly the
required theory. By this I mean in particular that it proves all lower bounds mentioned
above and, moreover, these formal proofs are obtained in a very natural and straightforward way.\textsuperscript{1} \cite[p.376]{53} $\mathsf{V}^1_1$ is a second-order variant of $\mathsf{PV}_1$.\textsuperscript{2} Proofs of (a)-(c) formalize in $\mathsf{V}^1_1$ and partly even below: (a) in a theory corresponding to $\mathsf{NC}$ via a now famous new proof of Håstad’s Switching Lemma \cite{25}, and (c) in a theory corresponding to circuits of a certain sublinear depth (see \cite{53} for precise statements).

We want to talk about circuit lower bounds for computational problems like the satisfiability problem $\mathsf{SAT}$, and therefore blurr the distinction between an explicit function $Q: \{0,1\}^* \to \{0,1\}$ and the computational problem $\{x \mid Q(x) = 1\}$.

It is not straightforward to formalize a size $s$ circuit lower bound

\begin{equation}
\text{For every circuit } C \text{ of size } s \text{ there exists } y \in \{0,1\}^n \text{ such that } C(y) \neq Q(y). \quad (1)
\end{equation}

in bounded arithmetic which lacks exponentiation. Razborov treats circuits as sets and inputs as numbers. In his words, this captures “the common practice in the area which tends to treat Boolean inputs and functions separately, as two different kinds of objects”.\cite[p.375]{53} We stick to the first-order setting, and $\mathsf{PV}_1$ instead of $\mathsf{V}^1_1$. There Razborov’s formalization assumes $2^{2^n}$ exists which allows to code $C$ by a number even for $s$ exponential in $n$. Note that the whole truth table of $Q$ on $\{0,1\}^n$ is coded by a number. Denote\textsuperscript{3} this formula by $\text{LB}_{\text{tt}}[Q].$

In Krajíček’s words, this formalization “differs from the one usually accepted in bounded arithmetic […] in which all combinatorial objects (inputs, circuits,...) are coded at the same level (by sets in the case of $\mathsf{V}^1_1$) while (Boolean) functions are identified with definable classes”. An according succinct formalization, assumes only that $2^n$ exists. It allows only to consider polynomial size bounds $s \leq n^k$ for some constant $k \in \mathbb{N}$. Denote such a formula by $\text{LB}[Q]$. More precisely, we have a formula $\text{LB}[C, Q](C, s, n, N)$ expressing a size $s$ lower bounds for circuits $C$ from the class $C$; it uses an auxiliary variable $N$ and supposes $n = |N|$.

The assumption that $2^n$ is the length of some number, intuitively means that the whole truth-table of $Q$ on $\{0,1\}^n$ is considered a feasible object. The succinct $\text{LB}$-formalization assumes only that $n$ is the length of some number. Intuitively, this means that only the size $\leq n^k$ of the circuit is considered feasible. For size bound $s = n^k$, the theory $\mathsf{PV}_1$ is in some sense exponentially stronger w.r.t. $\text{LB}_{\text{tt}}[Q]$ than it is w.r.t. $\text{LB}[Q]$. We now ask again for the right fragment to capture circuit lower bounds, this time in the succinct $\text{LB}$-formalization. This is the topic of the present paper.

\textsuperscript{1}Emphasis added by the authors. Additionally to our (a)-(c), Razborov refers to lower bounds for monotone formulas.

\textsuperscript{2}More precisely, the $\mathsf{RSUV}$-isomorphism (see e.g. \cite[Theorem 5.5.13]{32}) translates $\mathsf{V}^1_1$ into $\mathsf{S}^2_1$ which is $\Sigma^b_1$-conservative over $\mathsf{PV}_1$ (see Theorem 2.1).

\textsuperscript{3}All notions and notations are defined later.
1.2 Succinct circuit lower bounds in \( \text{APC}_1 \)

As a candidate we put forward Jeřábek’s theory \( \text{APC}_1 \) of approximate counting [28] which is a slight extension of \( \text{PV}_1 \) by the \((\text{dual or})\) surjective weak pigeonhole principle for polynomial time functions. While \( \text{PV}_1 \) formalizes polynomial time reasoning, \( \text{APC}_1 \) formalizes probabilistic polynomial time reasoning. Recalling Razborov’s quote, we aim at formalizations as close as possible to the original arguments. Some changes are, however, needed.

For (a) we formalize in \( \text{APC}_1 \) an argument close to Furst, Saxe and Sipser’s [23] based on probabilistic reasoning with random restrictions. Probabilities are estimated using Jeřábek’s notion of approximate counting, and doing so requires the construction of feasible surjections witnessing these estimations. That \( \text{APC}_1 \) proves the succinct formalization of (a) has already been shown by Krajíček [32, Theorem 15.2.3] formalizing Razborov’s abovementioned alternative proof of Håstad’s Switching Lemma. His proof is different and of independent interest.

Letting \( \text{AC}^d_0 \) denote the set of circuits of depth \( \leq d \), and \( \text{PARITY} \) denote the set of numbers whose binary expansion contains an odd number of ones, the formal statement reads as follows (see Theorem 3.7):

**Theorem 1.1.** Let \( d, k \in \mathbb{N} \). There is \( n_0 \in \mathbb{N} \) such that the theory \( \text{APC}_1 \) proves

\[
    n_0 \leq n \rightarrow \text{LB}[\text{AC}^d_0, \text{PARITY}](C, n^k, n, N).
\]

Razborov and Smolensky’s method for (b) typically requires to consider exponentially large objects such as the ring of \( n \)-variate polynomials over some finite field. In order to simulate the argument in \( \text{APC}_1 \) we compromise slightly on our aspired succinctness and assume a fixed quasi-polynomial function of \( n \) to be a length (formally expressed by “\( \in \text{Log} \)” below). As a consolation prize, this scaled down \( n \) allows to formulate and prove a lower bound for \( s = n^\log n \) instead just \( n^k \). Secondly, polynomials approximating formulas are not constructed directly but instead we construct succinct descriptions of them by arithmetical circuits.

Letting \( \text{AC}^d_0[p] \) denote the set of circuits of depth \( \leq d \) with \( \text{MOD}_p \)-gates, and \( \text{MOD}_q \) denote the set of numbers whose binary expansion contains a number of ones divisible by \( q \), the formal statement reads as follows (see Corollary 3.13):

**Theorem 1.2.** Let \( d \in \mathbb{N} \) and \( p \neq q \) be primes. There is \( n_0 \in \mathbb{N} \) such that the theory \( \text{APC}_1 \) proves

\[
    n_0 \leq 2^{\log^{9d} n} \in \text{Log} \rightarrow \text{LB}[\text{AC}^d_0[p], \text{MOD}_q](C, n^\log n, n, N).
\]

The proof [5] of the monotone circuit lower bound (c) is formalizable in \( \text{APC}_1 \) without essential change. However, here (and also in the proof of Theorem 1.2), we actually need to reason not directly in \( \text{APC}_1 \) but in a suitably conservative extensions.

Letting \( \text{MC} \) denote the set of all monotone circuits, and \( k\text{-CLIQUE} \) the set of (numbers coding) graphs with a clique of size \( k \), the formal statement reads as follows:
Theorem 1.3. Let \( d, k \in \mathbb{N} \). There is \( n_0 \in \mathbb{N} \) and a rational \( 0 < \epsilon < 1 \) such that the theory \( \text{APC}_1 \) proves

\[
n_0 \leq n \to \text{LB}[\text{MC}, k\text{-CLIQUE}](C, n^{\epsilon \sqrt{k}}, n, N).
\]

Actually, we prove a more general statement allowing for non-constant \( k \) – see Theorem 3.15.

We remark that a proof of \( \text{LB}[C, Q] \) in \( \text{APC}_1 \) gives a probabilistic polynomial time algorithm that witnesses errors of small \( C \)-circuits trying to decide \( Q \); see Section 3.5.

1.3 Independence and natural proofs

Recall that, informally, \( \text{PV}_1 \) formalizes proofs working with polynomial time computable concepts and constructions, and the central problem is whether \( \text{PV}_1 \) is able to prove general circuit lower bounds such as \( \text{LB}_{tt}[\text{SAT}] \) for \( s = n^k \).

As what can be seen as a partial negative answer Razborov and Rudich [56] observed that many lower bound proofs for an explicit function \( Q \) (e.g. (a) and (b)) do exhibit a feasible property of \( Q \) restricted to \( \{0,1\}^n \) which is not shared by functions computed by the circuit class under consideration. Moreover, this property is after all not that special to \( Q \) but true for random functions on \( \{0,1\}^n \) with non-negligible probability. Now, if strong pseudorandom generators exist, then such “natural proofs” for superpolynomial lower bounds against general circuits do not exist.

It has been suggested, amongst others by Razborov and Rudich themselves [56, Conclusions], that “the natural proof barrier should be regarded a hint, and not a barrier, to separating complexity classes” [16, p.1587] (see [15, 14] for proposals). In any case, the notion of naturality as a property of proofs is informal and it is questionable whether it could imply independence from \( \text{PV}_1 \). What Razborov [54] could show is that it rules out proofs in \( S_2^2(\alpha) \), a weak fragment of \( V_1^1 \) plus the smash function ([52, 33, 7] give alternative proofs based on propositional feasible interpolation).

We shall formalize the natural proof barrier itself (Theorem 3.26). We work in \( \text{APC}_1^+ \), a variant of \( \text{APC}_1 \) from [12], which allows for a relatively smooth formalization of the underlying concepts.

The succinct lower bound \( \text{LB}[\text{SAT}] \) for \( s = n^k \) is shown in [46] to be unprovable in a theory formalizing \( \text{NC}^1 \) reasoning unless subexponential size formulas can approximate polynomial size circuits. Relatedly, \( \text{LB}[Q] \) has been shown to be consistent with \( \text{PV}_1 \) for \( Q = \text{SAT} \) in [19] (improving upon [34]) unless the polynomial hierarchy collapses to the Boolean hierarchy, and recently [38] unconditionally for some \( Q \in \text{P} \).
1.4 Succinct tautologies

For every $n \in \mathbb{N}$ statement $\text{LB}_t[Q]$, say for $s = n^k$, translates to propositional formulas

$$\text{tt}[Q, n^k] := \bigvee_{a \in \{0,1\}^n} \text{"}C(a) \neq Q(a)\text{"},$$

where “$C(a) \neq Q(a)$” is a propositional formula with variables for the encoding of the circuit $C$ and its computation on $a$. The formula has size $2^{O(n)}$ and is tautological if and only if the lower bound is true.

It is well-known [18] that $\text{PV}_1$ is simulated by the Extended Frege system $\text{EF}$. In particular, Razborov’s [53] $\text{PV}_1$-proofs of (a)-(c) translate to short $\text{EF}$-proofs of the corresponding $\text{tt}$-tautologies. ‘Short’ means polynomial in the size of the tautology, i.e. $2^{O(n)}$. Unprovability of $\text{LB}_t[\text{SAT}]$ for $s = n^k$ in $\text{PV}_1$ is implied by (and roughly equivalent to) $\text{tt}[\text{SAT}, n^k]$ not admitting short $\text{EF}$-proofs. Consistency of the succinct formula $\text{LB}[\text{SAT}]$ with $\text{PV}_1$ is implied by lower bounds for $\text{EF}$ with constant advice (see [19, Theorems 6.8, 3.4]).

The $\text{tt}$-formulas are particular so-called $\tau$-formulas suggested as candidate hard tautologies independently by Alekhnovitch et al. [2] and Krajčí [35], and in some sense the hardest among them (cf. [36]). Not too much is known concerning lower bounds though. The natural proof barrier rules out short proofs of $\text{tt}[Q, n^\omega(1)]$ for sufficiently strong systems with feasible interpolation (cf. [37, Theorem 29.2.3]). Some unconditional lower bounds are known for weak systems with suitably written $\text{tt}[Q, n^k]$. Improving on earlier results of Raz [49] for Resolution, Razborov [55] proved a $2^{\Omega(1)}$ lower bound for $\text{tt}[Q, t]$ and $n^2 \leq t \leq 2^n$ in an extension of Resolution operating with $(\epsilon \cdot \log n)$-DNFs for small enough $\epsilon > 0$. We refer to the Introduction of [55] for a short survey, or to [37, Chapters 27–30] for a more comprehensive one.

We ask whether it is possible to feasibly construct propositional proofs of circuit lower bounds expressed succinctly. We study two ways to get such succinct formulas of size $n^{O(1)}$ or at least far smaller than $2^{O(n)}$.

The first is via the succinct formula $\text{LB}[Q]$ and has been discussed in [48]. Its quantifier complexity is too high to be canonically translated to tautologies, but if the existential quantifier on $y$ in (1) could be witnessed by a polynomial time or $\text{P/poly}$ function $w$, then it does translate to a tautology $\text{lb}_w$ of size $n^{O(1)}$. Such a function produces given a circuit $C$ an input string $y$ such that $C(y) \neq Q(y)$. Of course, the question whether such functions exist is of independent complexity theoretic interest. We observe that they do exist for $Q = \text{SAT}$ under plausible hardness assumptions (Proposition 4.8).

Our main result concerning $\text{lb}_w$-formulas is a general relative upper bound: we show that $\text{APC}_1$-proofs of succinct lower bounds give $\text{lb}_w$-formalizations such that there are short $\text{EF}$-proofs of $\text{lb}_w$ assuming that some function is hard for a specific circuit of subexponential size. We refer to Theorem 4.10 for a precise statement.

The second way is via Lipton and Young’s anticheckers [41] which allow to move to a size $n^{O(1)}$ subdisjunction of (2) which is still tautological. Intuitively, such a formula
should be even harder than the tt-formula because it has the same meaning but is exponentially more succinct. To support the intuition, we observe that hardness of the lavish tt-formulas for constant depth Frege implies hardness of the succinct tautologies for unrestricted Frege (Proposition 4.14).

A non-uniform variant of the anti-checked formula has variables for the bits $Q(a)$. It expresses a circuit lower bound for a partial function given by a partial truth table. Based on Razborov and Rudich's naturalization of Smolensky's proof of (b) we exhibit a property of such partial truth tables such that the lower bound formulas are tautological whenever a partial function with this property is substituted. We observe that there are many such functions and give a quasipolynomial time algorithm producing proofs of these tautologies in Jeřábek's proof system WF—it is to APC$_1$ as EF is to PV$_1$ [26]. We refer to Corollary 4.17 for a precise statement. In other words, we exhibit a succinct version of a natural property. Notably, this is also motivated by a generic learning task described in Section 4.5.

2 Preliminaries

2.1 The theory PV$_1$

The first theory formalizing polynomial time reasoning was introduced by Cook [18]. Its language PV contains $<$ and symbols for all polynomial time functions (over $\mathbb{N}$) introduced inductively according to Cobham's characterization [17, p.28]. We blur the distinction between the symbol and the function, that is, between the symbol and its interpretation in the standard model with universe $\mathbb{N}$.

Following [40], PV$_1$ is a universal theory in the language PV given by Cobham's equations and a scheme equivalent to induction

$$\varphi(0, \bar{x}) \land \forall y(\varphi(y, \bar{x}) \rightarrow (y + 1, \bar{x})) \rightarrow \varphi(x, \bar{x})$$

for $\varphi(x, \bar{x})$ quantifier-free. We refer to [32, Section 5.3] for a definition. In fact, PV$_1$ proves induction for formulas in $\Sigma^b_0 = \Pi^b_0$, i.e. PV-formulas with only sharply bounded quantifiers $\exists x < |t|, \forall x < |t|$, where $t$ is a PV-term without $x$ and $|z|$ denotes (in the standard model) the length of the binary representation of $z$. Inductively, $\Sigma^b_{i+1}$ (resp. $\Pi^b_{i+1}$) is the closure of $\Pi^b_i$ (resp. $\Sigma^b_i$) under positive Boolean combinations, sharply bounded quantification and $\exists x < t$ (resp. $\forall x < t$).

The theory $S^1_2 = S^1_2(PV)$ is obtained from PV$_1$ by adding length induction

$$\varphi(0, \bar{x}) \land \forall y(\varphi(y, \bar{x}) \rightarrow \varphi(y + 1, \bar{x})) \rightarrow \varphi(|x|, \bar{x})$$

for $\varphi(x, \bar{x}) \in \Sigma^b_1$. It is $\Sigma^b_1$-conservative over PV$_1$ by [6]:
**Theorem 2.1** (Buss’ Witnessing). If $S^1_2$ proves $\exists y \varphi(y, \bar{x})$ for $\varphi(y, \bar{x}) \in \Sigma^b_1$, then $PV_1$ proves $\varphi(f(\bar{x}), \bar{x})$ for some function symbol $f(\bar{x})$ in $PV$.

Let $n, m, N$ be variables. We write $n \in Log$ for $\exists N n = |N|$, and $n \in LogLog$ for $\exists N n = ||N||$. In a context where $n = |N|$ we write $2^n$ for $1\#N$. We view numbers below $2^n$ as $n$-bit strings. There is $eval \in PV$ denoting (in the standard model) the circuit evaluation function: for a circuit $C$ with $n$ inputs $C(x) := eval(C, x)$ for $x < 2^n$ is the value computed by $C$ on $x$; if $C$ has $m$ outputs then this value is a number $< 2^m$. The size of a circuit is the number of inner (non-input) gates. The following is folklore.

**Proposition 2.2.** For every $f \in PV$ there are $\ell, k \in \mathbb{N}$ such that the theory $PV_1$ proves for every $n \in Log$ that there exists a size $n^\ell$ circuit $C$ with $n$ inputs and $n^k$ outputs such that $f(x) = C(x)$ for all $x < 2^n$.

Like $2^n$ we use similar suggestive notation for other fast growing functions when applied to arguments $n = |N|$ in $Log$. For example, for $f \in PV$ we write $\sum_{i<n} f(i)$ for a $PV$-symbol $g(N)$ such that $PV_1$ proves $g(2N) = g(2N + 1) = g(N) + f(|N|)$. Similarly for $\prod_{i<n} f(i)$. For example, $PV_1$ proves $N = \sum_{i<n} bit(i, N)$ for a suitable bit $e \in PV$; we understand that $bit(i, N) = 0$ for $i \geq n$. Rationals $a/b$ are naturally coded by pairs and we use them freely in equations and inequalities. E.g. $a/b \in Log$ means $\exists c a/b \leq c \in Log$.

This allows to formally use $n!$ and $\binom{n}{i}$ for $i \leq n$. For example, $PV_1$ proves $\sum_{i=0}^{n} \binom{n}{i} = 2^n$.

We shall need the following less trivial calculations in $PV_1$.

**Proposition 2.3** (Stirling’s bound, Jeřábek [26]). There is a $c > 1$ such that $PV_1$ proves:

$$0 < k < n \in Log \rightarrow \frac{1}{c} \binom{n}{k} < \frac{n^n}{k^k(n-k)^{n-k}} \cdot \left(\left\lceil \frac{k(n-k)}{n} \right\rceil + 1 \right)^{-1} < c \binom{n}{k}.$$

**Proposition 2.4.** For every rational $\epsilon > 0$ there is an $n_0 \in \mathbb{N}$ such that $PV_1$ proves:

$$n_0 < n \in Log \rightarrow \sum_{i=0}^{\lfloor n/2+1/3 \rfloor} \binom{n}{i} < (1/2 + \epsilon) \cdot 2^n.$$

**Proof.** Argue in $PV_1$. We have

$$\sum_{i=0}^{\lfloor n/2 \rfloor - 1} \binom{n}{i} = \frac{1}{2} \left( \sum_{i=0}^{\lfloor n/2 \rfloor - 1} \binom{n}{i} + \sum_{i=0}^{\lfloor n/2 \rfloor - 1} \binom{n}{n-i} \right) < 2^{n-1}$$

and by Stirling’s bound, for some constant $c > 1$,

$$\sum_{i=\lfloor n/2 \rfloor}^{\lfloor n/2 + 1/3 \rfloor} \binom{n}{i} < (n^{1/3} + 1) \binom{n}{\lfloor n/2 \rfloor} < 2^n 4c \left( \frac{n^{1/3}}{\lfloor n/2 \rfloor} + 1 \right) \binom{\lfloor n/2 \rfloor}{\lfloor n/2 \rfloor/2} \left( \frac{n^{1/3}}{\lfloor n/2 \rfloor} + 1 \right),$$

where to verify the last inequality for odd $n$ we also used $(1 + a/b) \leq 4^{a/b}$ for $a, b \in Log$, $b > 0$ as shown in [26, Stirling’s bound, Claim 1].
Proposition 2.5. PV₁ proves:

\[ n + 1 < m \in \text{Log} \implies (m - n)^n \leq m^m / 2^n \wedge (1 - n/m) \leq 2^{-n/m}. \]

Proof. Note the second conjunct of the conclusion follows from the first. Proceed as in the proof of Claim 2 in [26, Stirling’s bound, Claim 1] but instead of Claim 1 use the inequality \( m^m \leq (m + 1)^m / 2. \)

2.2 Two formalizations of circuit lower bounds

As outlined in the introduction we give two PV₁-formulas expressing a size \( s \) lower bound for circuits from a class \( C \) computing a function \( f : \mathbb{N} \to \{0, 1\} \) on (numbers smaller than) \( 2^n \) which play the role of binary strings of length \( n \).

We assume throughout that the class of circuits \( C \) is in polynomial time, and more precisely, that it is defined (in the standard model) by a \( \Sigma^b_0 \)-formula. In particular,

\[ “C \text{ is a C-circuit of size } \leq s” \]

is a \( \Sigma^b_0 \)-formula with free variables \( C \) and \( s \).

The two formalizations use a dummy variable \( N \) which the formulas suppose to be either such that \( 2^n = |N| \) or such that \( n = |N| \). In the intuitive mode of speech from the introduction, the different scalings used by the two formulas are thus made explicit.

The two formulas can be obtained following two ways of how to make one’s mind about the “a little bit annoying”[53, p.377] problem of what is meant by an explicit function \( f \). The first is to assume \( n \in \text{LogLog} \), so \( f \) restricted to (numbers smaller than) \( 2^n \) is given by a number whose binary expansion codes its truth table:

\[
\begin{align*}
\text{LB}_{tt}[C](f, C, s, n, N) &:= \exists y < |N| \ \text{LB}^0_{tt}[C](f, C, s, n, N, y), \\
\text{LB}^0_{tt}[C](f, C, s, n, N, y) &:= \left( 2^n = |N| \implies (C \text{ is a C-circuit of size } \leq s \implies C(y) \neq \text{bit}(y, f)) \right).
\end{align*}
\]

Recall \( C(y) \) abbreviates \( \text{eval}(C, y) \). The antecedens \( 2^n = |N| \) defines a polynomial time relation between \( n \) and \( N \) and can thus be represented by a \( \Sigma^b_0 \)-formula. Thus \( \text{LB}_{tt}[C](f, C, sn, N) \) is \( \Sigma^b_0 \).

Somewhat less explicitly, one views \( f \) as the characteristic function of the computational problem \( Q := f^{-1}(1) \) and uses a formula defining \( Q \). We denote this formula by \( Q(y) \). Such a formalization works supposing only \( n \in \text{Log} \). More precisely, define

\[
\begin{align*}
\text{LB}[C, Q](C, s, n, N) &:= \exists y < 1 \# N \ \text{LB}^0[C, Q](C, s, n, N, y), \\
\text{LB}^0[C, Q](C, s, n, N, y) &:= \left( n = |N| \implies (C \text{ is a C-circuit of size } \leq s \implies (C(y) = 1 \oplus Q(y))) \right).
\end{align*}
\]
Here, $\oplus$ denotes exclusive disjunction. Note that the existential quantifier on $y$ is not sharply bounded anymore. If $Q \in P$ or $Q \in \text{NP}$, then the formula $Q(x)$ can be chosen $\Sigma_0^b$ or $\Sigma_1^b$ respectively, and then $\text{LB}[C,Q](C,s,n,N)$ becomes $\Sigma_0^b$ and $\Sigma_1^b$ respectively.

We do not mention $C$ if it is the class of all circuits, so the resulting formulas are denoted $\text{LB}_{\text{tt}}$, $\text{LB}_0^{\text{tt}}$, $\text{LB}[Q]$, $\text{LB}^0[Q]$.

Remark 2.6. Corresponding to Razborov’s formulas [53] mentioned in the introduction, a truth table formalization of a circuit lower bound for a fixed problem $Q$ would read

$$\text{LB}_{\text{tt}}[C,Q](C,s,n,N) := \text{LB}[C,Q](C,s,n,|N|)$$

in our formalism. We are not going to use these formulas.

Note a circuit of size $s$ is coded by a number of length $O(s \cdot |s|)$, so formally quantifying over circuits of size $\leq s$ is meaningful only for $s \in \text{Log}$. In the $\text{LB}_{\text{tt}}$-formula this allows $s \leq 2^{(1-o(1))n}$ while the $\text{LB}$-formula allows only $s = n^{O(1)}$. We repeat the intuition from the introduction for $s \leq n^{O(1)}$. Choosing the scale of $n$ means choosing the “feasible object”. In the $\text{LB}_{\text{tt}}$-formulas $n \in \text{LogLog}$, so the truth-table (and everything polynomial in it) is feasible. The $\text{LB}$-formalization just assumes that $n \in \text{Log}$. This means that only the objects of polynomial-size in $(n$ or) the size of the circuit are feasible. Likewise, a theory reasoning about the circuit lower bound becomes less resp. more powerful when working with $\text{LB}$ resp. $\text{LB}_{\text{tt}}$.

2.3 The theory $\text{APC}_1$

We want to formally talk about the size of bounded definable sets $X = \{x < a \mid \varphi(x, \bar{x})\}$. These are not formal objects in our first-order language but a mode of speech: we let $x \in X$ stand for $(x < a \land \varphi(x, \bar{x}))$. We write $X \subseteq a$ instead $X \subseteq [0,a)$. We often write $a$ instead $[0,a)$; for a rational $a$, this means $[0,\lfloor a \rfloor)$. With $X \subseteq a$, $Y \subseteq b$, also

$$X \dot\cup Y := X \cup \{y + a \mid y \in Y\} \subseteq a + b,$$

$$X \times Y := \{bx + y \mid x \in X, y \in Y\} \subseteq ab,$$

are definable; we write $(x,y)$ for $bx + y$ in such a context.

In $\text{PV}_1$ ‘small’ sets can be counted precisely in the sense that every definable $X \subseteq n$ for $n \in \text{Log}$ is coded by a number $\gamma X\gamma$ and hence bijective via some coded bijection to a unique number $\text{Card}(\gamma X\gamma)$ which we write as $\text{Card}(X)$ (see e.g. [32, Section 5.4]). Obviously, if $\text{sWPHP}(\text{PV})$ fails, then there is no reasonable notion of size for ‘large’ definable sets $X \subseteq 2^n$, even quantifier free, i.e. circuit definable: $X = \{x < 2^n \mid C(x) = 1\}$ for a circuit $C$ with $n$ variables. Complexity theory in models of $\text{PV}_1$ where $\text{sWPHP}(\text{PV}_1)$ fails is studied in [31]. Here, $\text{sWPHP}(\text{PV})$ is the surjective weak pigeonhole principle for $\text{PV}$-functions: the set containing the formula

$$\text{sWPHP}(f) := (x > 0 \rightarrow \exists v < x(|y| + 1) \forall u < x |y| \ f(u, \bar{x}) \neq v).$$

(9)
for each \( f(u, \bar{x}) \in \mathsf{PV} \). Equivalently one can take the single formula obtained by replacing \( f(u, \bar{x}) \) with \( C(u) = \text{eval}(C, u) \) (Proposition 2.2).

Following the notation of [12], we are led to consider

\[
\mathsf{APC}_1 := \mathsf{PV}_1 + \mathsf{sWPHP}(\mathsf{PV}).
\]

In the Introduction we informally referred to \( \mathsf{APC}_1 \) as a “slight” extension of \( \mathsf{PV}_1 \). One reason is that \( \mathsf{sWPHP}(\mathsf{PV}) \) is provable in \( T_2^2 \) [42], so \( \mathsf{APC}_1 \) is quite low in the hierarchy of bounded arithmetics. But \( \mathsf{APC}_1 \) appears to be considerably weaker than \( T_2^2 \) (see [11, 4] for recent results). In terms of witnessing the step from \( \mathsf{PV}_1 \) to \( \mathsf{APC}_1 \) is that from polynomial time to probabilistic polynomial time. This is due to Wilkie and first published in [32, Theorem 7.3.7]. An alternative proof has been given by Thapen [59, Theorem 4.2], which, as observed in [26, Corollary 1.15], also yields the first statement in:

**Theorem 2.7** (Wilkie’s witnessing). \( S_2^1 + \mathsf{sWPHP}(\mathsf{PV}) \) is \( \Sigma^b_1 \)-conservative over \( \mathsf{APC}_1 \). If one of these theories proves \( \exists y \varphi(y, \bar{x}) \) for \( \varphi(y, \bar{x}) \in \Sigma^b_1 \), then there exists a probabilistic polynomial time Turing machine which given a tuple \( \bar{n} \) from \( \mathbb{N} \) outputs with probability at least \( 2/3 \) some \( m \in \mathbb{N} \) such that \( \varphi(m, \bar{n}) \) is true in the standard model.

The probability \( 2/3 \) can be boosted and the probabilistic computation is definable in some suitable sense – see [26]. Formal approximate counting has been developed by Jeřábek in his PhD Thesis [27] and a sequence of papers [26, 28, 29, 30]. In particular, [28] showed that \( \mathsf{APC}_1 \) supports a well-behaved notion of approximate size.

**Definition 2.8** (in \( \mathsf{PV}_1 \)). Let \( n, m \in \log \), and \( X \subseteq 2^n \) and \( Y \subseteq 2^m \) be definable. For a circuit \( C \) with \( n \) variables and \( m \) output gates, we write

\[
C : X \rightarrow Y
\]

for \( \forall y \in Y \exists x \in X C(x) = y \). For \( 0 \leq \epsilon \leq 1 \) define \( Y \preceq_{\epsilon} X \) if and only if there exist a circuit \( C \) and \( v \neq 0 \) such that

\[
C : v \times (X \cup \epsilon 2^n) \rightarrow v \times Y.
\]

We say \( C \) witnesses \( Y \preceq_{\epsilon} X \). Further, \( X \approx_{\epsilon} Y \) means \( (X \preceq_{\epsilon} Y \wedge Y \preceq_{\epsilon} X) \).

One easily checks (in \( \mathsf{PV}_1 \)) that \( X \subseteq Y \) implies \( X \preceq_0 Y \), and that \( (X \preceq_{\epsilon} Y \wedge Y \preceq_{\delta} Z) \) implies \( X \preceq_{\epsilon + \delta} Z \). The main result of [28, Theorem 2.7] implies that in \( \mathsf{APC}_1 \) every circuit definable set does have an approximate cardinality. Moreover, this is witnessed by invertible circuits. A circuit \( C : a \rightarrow b \) is invertible if there is a circuit \( D \) such that

\[
\forall z < b (D(z) < a \wedge C(D(z)) = z). \]

**Theorem 2.9.** The theory \( \mathsf{APC}_1 \) proves that for all \( n, \epsilon^{-1} \in \log \) and every circuit definable \( X \subseteq 2^n \) there exists \( s \leq 2^n \) such that \( X \approx_{\epsilon} s \). Moreover, both \( X \preceq_{\epsilon} s \) and \( X \gtrsim_{\epsilon} s \) are witnessed by invertible circuits.
The proof uses the Nisan-Wigderson generator \[44\] to sample \(X\) and thus get an estimate of its size. It is for this “production of magic surjections” \[30, p.842\] why the “extra complication is necessary” \[28, p.963\] to make \(v\) copies in Definition 2.8. This theorem allows to show \[28, Lemma 2.11\]:

**Proposition 2.10.** The theory APC\(_1\) proves for all circuit definable \(X, Y \subseteq 2^n\) and \(s, t, u \leq 2^{|a|}\) and \(\epsilon, \delta, \theta, \gamma < 1\) with \(\gamma^{-1} \in \text{Log}\):

(i) \(X \preceq_{\gamma} Y\) or \(Y \preceq_{\gamma} X\),

(ii) If \(s \preceq_{\epsilon} X \preceq_{\delta} t\), then \(s < t + (\epsilon + \delta + \gamma)2^n\),

(iii) If \(X \preceq_{\epsilon} Y\), then \(2^n \setminus Y \preceq_{\epsilon+\gamma} 2^n \setminus X\),

(iv) If \(X \approx_{\epsilon} s\) and \(Y \approx_{\delta} t\) and \(X \cap Y \approx_{\theta} u\), then \(X \cup Y \approx_{\epsilon+\delta+\theta+\gamma} s + t - u\).

The definition of \(\preceq\) is an unbounded \(\exists \Pi^b_2\)-formula so cannot be used freely in bounded induction. Jeřábek defines a conservative extension HARD\(_A\) of APC\(_1\) that has a function symbol for approximate cardinality allowed to be used in induction formulas (see \[26, Section 4\] and \[28, Theorem 2.13\]). Having induction allows to prove \[28, Proposition 2.15\] and \[28, Proposition 2.16\] (the version with \(\preceq\) replacing \(\succ\)):

**Proposition 2.11** (Disjoint union). The theory APC\(_1\) proves for \(\epsilon, \delta \leq 1\) and \(n, m, \delta^{-1} \in \text{Log}\) and a sequence of circuits defining a sequence \((X_i)_{i < m}\) of subsets of \(2^n\) and a sequence \((s_i)_{i < m}\): if \(X_i \preceq_{\epsilon} s_i\) for all \(i < m\), then \(\bigcup_{i < m}(X_i \times \{i\}) \preceq_{\epsilon+\delta} \sum_{i < m} s_i\).

**Proposition 2.12** (Averaging). The theory APC\(_1\) proves for \(\epsilon, \delta \leq 1\) and \(n, m, \gamma^{-1} \in \text{Log}\) and circuit definable \(Z \subseteq 2^n \times 2^m\) and \(Y \subseteq 2^m\) and all \(a, b\) the following. If \(Y \succ_{\epsilon} b\) and \(\{x < 2^n \mid \langle x, y \rangle \in Z\} \succ_{\delta} a\) for all \(y \in Y\), then \(Z \cap (2^n \times Y) \succ_{\epsilon+\delta+\epsilon\delta+\gamma} ab\).

### 3 Succinct circuit lower bounds in APC\(_1\)

#### 3.1 Approximate probabilistic reasoning

Approximate counting can be formulated as approximate probabilistic reasoning.

**Definition 3.1** (in APC\(_1\)). For circuit definable \(X \subseteq 2^{|l|}\) and \(Z \subseteq 2^{|l|} \times 2^{|s|}\) and \(0 \leq \epsilon, p \leq 1\) define

\[
\Pr_{x < t} [x \in X] \preceq_{\epsilon} p \iff \{x \in X \mid x < t\} \preceq_{\epsilon} pt,
\]

\[
\Pr_{x < t \atop y < s} [(x, y) \in Z] \preceq_{\epsilon} p \iff \{\langle x, y \rangle \in Z \mid x < t, y < s\} \preceq_{\epsilon} pts
\]

(recall \(\langle x, y \rangle = x2^{[s]} + y\)). We use similar notation for \(\succ_{\epsilon}\) and \(\approx_{\epsilon}\).
Applying Proposition 2.10 (iii) yields $$v$$.

Proof. (i): note $$\Pr$$ proves the following statements for $$0 \leq \epsilon, \delta, \gamma, p, q < 1, m, \gamma^{-1} \in \log$$, circuit definable sets $$X, Y \subseteq 2^{[t]}$$ and $$Z \subseteq 2^{[t]} \times 2^{[s]}$$, a sequence $$(X_i)_{i < m}$$ of subsets of $$2^{[t]}$$ given by a sequence of circuits, and a sequence $$(p_i)_{i < m}$$ of rationals.

(i) If $$\Pr_{x < t}[x \in X] \leq \epsilon + \delta p$$, then $$\Pr_{x < t}[x \in X] \leq \epsilon + 2\delta$$.

(ii) If $$\Pr_{x < t}[x \in X] \leq \epsilon + \delta$$, then $$\Pr_{x < t}[x \in X] \leq \epsilon + \delta p$$.

(iii) If $$\Pr_{x < t}[x \in X] \leq \epsilon$$ and $$\Pr_{x < t}[x \in Y] \leq \delta$$, then $$\Pr_{x < t}[x \in X \cup Y] \leq \epsilon + \delta + \frac{q}{2}$$.

(iv) If $$\Pr_{x < t}[x \in X] \leq \epsilon$$, then $$\Pr_{x < t}[x \in X] \leq \epsilon + \frac{q}{2}$$.

Proof. (i): note $$\Pr_{x < t}[x \in X] \leq \epsilon + \delta p$$ means there are $$v > 0$$ and a circuit computing a surjection from $$v \times (pt + (\epsilon + \delta)2^{[t]})$$ onto $$v \times (X \cap t)$$. But note the domain is a subset of $$v \times (pt + 2\delta t + \epsilon 2^{[t]})$$. The second statement is similar.

(ii) the first statement is easy and the second follows from Proposition 2.11.

(iii): we only show the first statement. If $$\Pr_{x < t}[x \in X] \leq \epsilon$$, then

$$(X \cap t) \cup [t, 2^{[t]}] \leq \epsilon \cdot [pt] \cup [t, 2^{[t]}].$$

Applying Proposition 2.10 (iii) yields

$$[(1 - p)t] \leq 0 \cdot [pt] \cup [t, 2^{[t]}] = 2^{[t]} \setminus (\cdot ) \leq \epsilon + \gamma 2^{[t]} \setminus ((X \cap t) \cup [t, 2^{[t]}]) = t \setminus X.$$

(iv): the second statement follows knowing the first and (iii) for all $$\gamma^{-1} \in \log$$. We prove the first statement only in the interesting case that $$2^{[t]} \cdot ts \geq 1$$ (otherwise $$ts \in \log$$). Assume $$\Pr_{x < t,y < s}[(x,y) \in Z] \leq \epsilon$$ and note this means

$$\tilde{Z} := \{(x,y) \in Z \mid x < t, y < s\} \leq \epsilon \cdot p t s.$$

Appealing to (i), it suffices to show for arbitrary $$\gamma^{-1} \in \log$$ that

$$\{x \mid (x,y) \in \tilde{Z}\} = \{x \mid (x,y) \in Z\} \cap t \leq \epsilon + \gamma \cdot p t$$

for some $$y < s$$, where we abbreviate $$\tilde{p} := p + (8\epsilon + 13\gamma)$$. But if there is no such $$y < s$$, then $$\{x \mid (x,y) \in \tilde{Z}\} \geq \epsilon + \gamma \cdot \tilde{p} t$$ for all $$y < s$$ by Proposition 2.10 (i). Applying Proposition 2.12 (with $$Y := [0, s), a := \tilde{p} t, \epsilon := 0, \delta := \epsilon + \gamma, \gamma := \gamma$$) yields

$$\tilde{Z} = \tilde{Z} \cap (2^{[t]} \times s) \geq \epsilon + 2\gamma \cdot \tilde{p} t s.$$

(11)
Proposition 2.10 (ii) applied to (10) and (11) gives

\[ \left\lfloor \tilde{\text{pts}} \right\rfloor < \left\lfloor \text{pts} \right\rfloor + (2\epsilon + 3\gamma) \cdot 2^{\left| t \right| + |s|}. \]

But the r.h.s. is \( \leq \left\lfloor \text{pts} \right\rfloor + (2\epsilon + 3\gamma) \cdot 2t \cdot 2s \leq \tilde{\text{pts}} - \gamma \cdot ts \), a contradiction if \( \gamma \cdot ts \geq 1. \)

**Remark 3.3.** Note that (i) and the first statement of (ii) do not require \( \text{sWPHP} (\text{PV}). \)

### 3.2 Parity lower bound for \( \text{AC}^0 \) circuits via random restrictions

By an \( \text{AC}^0_d \)-circuit, where \( d \in \mathbb{N} \), we mean a depth \( \leq d \) unbounded fan-in circuit with gates labeled \( 0, 1, \neg, \wedge, \vee \). The depth is the maximum length (number of edges) of a path from an input gate to an output gate. By the size of a circuit we mean the number of its inner gates. We formalize in \( \text{APC}_1 \) a lower bound for such circuits computing the parity function via a Switching Lemma which we prove by approximate probabilistic reasoning with random restrictions. Our argument is close to the one presented in [23]. We code restrictions as follows.

For \( n \in \text{Log} \) and a (formal) rational \( 0 \leq a/b \leq 1 \) we code a restriction of \( n \) propositional variables \( x_1, \ldots, x_n \) by the number \( \rho = \sum_{i=0}^{n-1} r_i (2b)^i, r_i < 2b \), and use the following suggestive notation that takes \( a, b \) understood from context: \( \rho(x_i) = x_i \) means \( r_i \in [0, 2a) \); \( \rho(x_i) = 1 \) means \( r_i \in [2a, b + a) \), and \( \rho(x_i) = 0 \) means \( r_i \in [b + a, 2b) \). If \( \rho(x_i) = x_i \) we say \( \rho \) leaves \( x_i \) unassigned; note that for \( a = 1 \) this means \( r_i < 2 \).

The notation \( \rho \sim R_{a/b} \) stands for \( \rho < (2b)^n \). It is straightforward to construct, for \( 1 \leq i \leq n \), the circuits witnessing

\[
\Pr_{\rho \sim R_{a/b}} [\rho(x_i) = x_i] \approx_0 \frac{a}{b},
\]

\[
\Pr_{\rho \sim R_{a/b}} [\rho(x_i) = 1] \approx_0 \frac{1 - a/b}{2} \approx_0 \Pr_{\rho \sim R_{a/b}} [\rho(x_i) = 0].
\]

If \( C = C(x_1, \ldots, x_n) \) is a circuit in at most the variables listed, then \( C \upharpoonright \rho \) is the circuit \( C(\rho(x_1), \ldots, \rho(x_n)) \) obtained by relabeling input gates as indicated. Given yet another restriction \( \rho' \in R_{a'/b'} \) we write \( C \upharpoonright \rho \rho' \) for \( (C \upharpoonright \rho) \upharpoonright \rho' \).

**Definition 3.4.** A DNF \( C \) depends on \( > b \) variables if there does not exist a sequence of \( b \) (not necessarily distinct) variables with the property that every assignment to it either satisfies (all literals in) some disjunct or falsifies (at least one literals in) each disjunct. For CNFs this is analogously defined.

Note that for fixed standard \( b \in \mathbb{N} \) the characteristic function of this property is in \( \text{PV} \). This ensures the existence of circuits defining events involving this property, as required by approximate counting in \( \text{APC}_1 \).

In the following we understand that irrational terms are rounded down on the innermost level unless specified otherwise, e.g. \( (1/n^{1/2})^c \) is \( (1/\lfloor n^{1/2} \rfloor)^c \) and \( 2 \log n \) is \( 2 \lfloor \log n \rfloor \).
Lemma 3.5 (Switching Lemma). For every $k \in \mathbb{N}$ there are $b, n_0 \in \mathbb{N}$ such that $\text{APC}_1$ proves: for every $n_0 < n, \epsilon^{-1} \in \text{Log}$ and DNF $D_n(x_1, \ldots, x_n)$ of size $n^k$:

$$\Pr_{\rho_1 \sim R_{1/n^{1/2}}, \rho_2 \sim R_{1/n^{1/4}}} [D_n | \rho_1 \rho_2 \text{ depends on } > b \text{ variables}] \leq \epsilon \frac{1}{n^{2k}}.$$ 

The same holds for CNFs.

Proof. We prove the lemma for DNFs, the second statement follows from the first. We follow a familiar proof of the switching lemma estimating the probabilities that formulas simplify under random restrictions. The probabilities are approximated by $\leq \epsilon$. The extra work then boils down to the construction of surjections witnessing the inequalities $\leq \epsilon$. These constructions are postponed to the end of the proof.

Let $n$ be sufficiently large and $n, \epsilon^{-1} \in \text{Log}$. Set $d := 3k$. Then

$$\Pr_{\rho_1} \left[ \rho_1 \text{ does not falsify all disjuncts in } D_n \text{ of size } \geq d \log n \right]$$

$$\leq n^k \cdot \left(1 - \frac{1 - 1/n^{1/2}}{2}\right)^{d \log n} \leq n^k \cdot \left(1 - \frac{1}{4}\right)^{d \log n} \leq 1/n^{3k}, \quad (12)$$

where we understand $\rho_1 \sim R_{1/n^{1/2}}$. Set $c := 12k + 3d$. Then

$$\Pr_{\rho_1} \left[ \rho_1 \text{ leaves } \geq c \text{ variables in some size } \leq d \log n \text{ disjunct of } D_n \text{ unassigned} \right]$$

$$\leq n^k \cdot \left(\frac{1}{n^{1/2}}\right)^c \cdot 2^{d \log n} \leq 1/n^{3k} \quad (13)$$

where for simplicity we bound $\lfloor n^{1/2} \rfloor$ by $n^{1/3}$ when rounding.

Therefore, by the first statement of Lemma 3.2 (ii), the probability that $D_n | \rho_1$ after a trivial simplification is not a $c$-DNF is $\leq_0 2/n^{3k}$. Now it suffices to show:

Claim 3.6. For any $c' \leq c$, there are $b_{c'}, n_{c'} \in \mathbb{N}$ such that $\text{APC}_1$ proves: for every $n_{c'} \leq n, \epsilon^{-1} \in \text{Log}$ and $c'$-DNF $D_{n'}(x_1, \ldots, x_n)$,

$$\Pr_{\rho_2} \left[ D_{n'} | \rho_2 \text{ depends on } > b_{c'} \text{ variables} \right] \leq b_{c'} \epsilon \frac{b_{c'}}{n^{3k}}.$$ 

Similarly as above, we understand $\rho_2 \sim R_{1/n^{1/4}}$. To prove the claim we proceed by induction on $c'$. If $c' = 0$, the claim holds trivially. Assume that $c' > 0$ and the claim holds for $(c' - 1)$-DNFs, we want to show that it holds for $c'$-DNFs. Let $S$ be a sequence of conjunctions, namely $D_{n'}$-disjuncts, with disjoint variables which is maximal in the sense that adding any other disjunct to $S$ would break the disjointness property (we are not asking for a maximum length such sequence since finding one could be hard for $\text{APC}_1$).
Set $d' := 4^{c'} 4k$. In case $S$ contains $\geq d' \log n$ conjunctions, then, using Proposition 2.5,

$$\Pr_{\rho_2} [\rho_2 \text{ does not satisfy any conjunction in } S] \lesssim \epsilon \left( 1 - \left( \frac{1 - 1/n^{1/4}}{2} \right)^{c'} d' \log n \right) \leq 2^{-d' \log n / 4^{c'}} \leq 1/n^{3k}. \quad (14)$$

where the choice of $d' = 4^{c'} 4k$ instead of $d' = 4^{c'} 3k$ is again taking care of rounding. In case $S$ contains $< d' \log n$ conjunctions, then (bounding $\lfloor n^{1/4} \rfloor$ by $n^{1/5}$)

$$\Pr_{\rho_2} [\rho_2 \text{ leaves } > 15k \text{ variables in } S \text{ unassigned}] \lesssim_0 \left( \frac{1}{n^{1/4}} \right)^{15k+1} \cdot \left( c' d' \log n \right) \frac{2^{15k} \cdot b_{c'-1}}{n^{3k}} \leq \frac{1}{n^{3k}}. \quad (15)$$

As every $D_n'$-disjunct outside $S$ shares a variable with some conjunction in $S$, by setting all variables in $S$ we get a $(c' - 1)$-DNF which by the induction hypothesis depends on $> b_{c'-1}$ variables with probability $\lesssim b_{c'-1} / n^{3k}$. By $2^{15k}$ applications of the first statement in Lemma 3.2 (ii), $D_n' \mid \rho_2$ depends on $> 15k + 2^{15k} \cdot b_{c'-1} =: b_{c'}$ variables with probability

$$\lesssim 2^{15k} \cdot b_{c'-1} \cdot \epsilon \cdot 2^{15k} \frac{b_{c'-1}}{n^{3k}} + \frac{1}{n^{3k}}.$$

which proves the claim.

It remains to describe circuits witnessing the estimations (12)-(15).

(12) We are asked to map every

$$z < n^k \cdot \left( 1 - \frac{1 - 1/n^{1/2}}{2} \right)^{d \log n} \cdot (2n^{1/2})^n = n^k \cdot (n^{1/2} + 1)^{d \log n} \cdot (2n^{1/2})^{n-d \log n}$$

to some $\rho_1 < (2n^{1/2})^n$ in such a way that every $\rho_1$ which does not falsify all size $\geq d \log n$ conjunctions in $D_n$ is in the image of the mapping. A given such $z$ determines a triple $(s, p, r)$ with

$$s < n^k,$$

$$p = \sum_{i<d \log n} \epsilon_i \cdot (n^{1/2} + 1)^i \quad \text{with } \epsilon_i < n^{1/2} + 1,$$

$$r = \sum_{i<n-d \log n} r_i \cdot (2n^{1/2})^i \quad \text{with } r_i < 2n^{1/2}.$$

Output the restriction $\rho_1$ that assigns the first $d \log n$ variables in the $s$-th disjunct of $D_n$ according to $\epsilon_0, \ldots, \epsilon_{d \log n-1}$ so that the disjunct is not falsified and the rest according to $r_0, \ldots, r_{n-d \log n-1}$.
(13) A given $z < n^{k-c/2} 2^{d \log n} (2n^{1/2})^n$ determines $(s, t, p, r)$ with $s < n^k, t < 2^c, p < 2^{d \log n}$ and $r < (2n^{1/2})^{n-c}$. Output the restriction $\rho_1$ that assigns, for the maximal $c_0$ possible, the first $c_0 \leq c$ variables in the $s$-th disjunct of $D_n$ on the positions specified by $p$ according to $t$ (these variables are left unassigned by $\rho_1$), and the rest of variables according to $r$ together with the unused part of $t$.

(14) Let $T$ be a conjunction of literals in $t \leq c'$ variables $y_1, \ldots, y_t$, and let $\rho_3 \sim R_{1/n^{1/4}}$ be defined for these variables (i.e. $\rho_3 < (2n^{1/4})^t$). The probability that such a $\rho_3$ satisfies $T$ is $\approx_0 (\frac{1-1/n^{1/4}}{2})^t \geq (\frac{1-1/n^{1/4}}{2})^{c'}$. By Lemma 3.2 (iii),

$$\Pr_{\rho_3}[\rho_3 \text{ does not satisfy } T] \approx \epsilon/(d' \log n) - \left(1 - \frac{1-1/n^{1/4}}{2}\right)^{c'}.$$ 

Let $C_T$ be a circuit witnessing this inequality. Note there are only standard finitely many conjunctions $T$ of the considered type.

To prove (14) we have to map numbers

$$z < \left(1 - \left(\frac{1-1/n^{1/4}}{2}\right)^{c'}\right)^{d' \log n} (2n^{1/4})^n$$

to $\rho_2 \sim R_{n^{1/4}}$ such that all restrictions that do not satisfy any conjunction in $S$ are hit. Assume for notational simplicity that $S$ contains exactly $d' \log n$ conjunctions and let $j$ range over numbers between 1 and $d' \log n$. View a given $z$ as a pair of a sequence $(z_j)_j$ and $r$ where

$$z_j < \left(1 - \left(\frac{1-1/n^{1/4}}{2}\right)^{c'}\right) (2n^{1/4})^{t_j},$$

$$r < (2n^{1/4})^{n-\sum_j t_j}.$$ 

Here, $t_j$ is the number of variables appearing in the $j$-th disjunct in $S$. Output $\rho_2$ which sets the variables not occurring in $S$ according to $r$; to set a variable occurring in $S$, say, the $i$-th variable in the $j$-th conjunction of $S$ (hence $1 \leq i \leq t_j \leq c'$), first choose a conjunction $T$ from the finite list of conjunctions considered above such that the $j$-th conjunct is a suitable variable substitution of $T$; then assign the given variable as the restriction $C_T(z_j)$ assigns its $i$-th variable.

(15) Given $z$ coding the triple $(s, t, r)$ with $s < 2^{15k+1}, t < (c'd' \log n)_{15k+1}$ and $r < (2n^{1/4})^{n-15k-1}$, output the restriction $\rho_2$ assigning, for the maximal $c_0$ possible, the first $c_0 \leq 15k+1$ variables in $S$ specified by the $t$-th $(15k+1)$-size subset of $c'd' \log n$ according to $s$ (these variables are left unassigned) and the rest according to $r$ together with the unused part of $s$. 

\[\square\]
Theorem 3.7. For all $k, d \in \mathbb{N}$ there is $n_0 \in \mathbb{N}$ such that $\text{APC}_1$ proves: for all $n_0 < n \in \text{Log}$ and every $\text{AC}^0_d$-circuit $C_n$ of size $n^k$ with $n$ variables there is $y < 2^n$ such that $C_n(y) \neq \sum_{i=1}^n \text{bit}(i-1,y) \mod 2$.

Proof. There is a $\text{PV}$-function transforming any $n^k$-size circuit $C_n$ of depth $d$ into an equivalent $C'_n$ circuit of size $n^k + n - 1 \leq n^{2k}$, depth $d$ and with negations appearing only at the variables. The equivalence is proven in $\text{PV}_1$ for each fixed assignment by $\Sigma_0^b$-induction on the number of gates in $C_n$.

By Lemma 3.5 there is a (standard) $b \in \mathbb{N}$ such that for any DNF or CNF $C$ at the bottom level of $C'_n$, we have that $C|_{\rho_1 \rho_2}$ depends on $> b$ variables with probability $\leq \epsilon 1/n^{4k}$; here $\epsilon$ is chosen ‘small enough’ with inverse in $\text{Log}$. By Lemma 3.2 (ii), this event happens for some bottom level DNF or CNF only with probability $\leq 2\epsilon 1/n^{2k}$.

We further claim, understanding $\rho_1 \sim R_{1/n^{1/2}}$ and $\rho_2 \sim R_{1/n^{1/4}}$,

$$\Pr_{\rho_1 \rho_2} \left[ \text{there are } < n^{1/8} \text{ variables left unassigned by both } \rho_1 \text{ and } \rho_2 \right]$$

$$\leq 0 \cdot n^{n^{1/8}} \cdot \left(1 - \frac{1}{n^{3/4}}\right)^{n-n^{1/8}} \leq n^{n^{1/8}} \cdot 2^{-\frac{(n-n^{1/8})}{n^{3/4}}} \leq n^{n^{1/8}} \cdot 2^{1-n^{1/4}} \leq 1/n^{2k}.$$  

The first $\leq$ uses Proposition 2.5. To witness $\leq 0$ we map

$$z < n^{n^{1/8}} \cdot \left(1 - \frac{1}{n^{3/4}}\right)^{n-n^{1/8}} \cdot (2n^{1/2})^{m} \cdot (2n^{1/4})^{n} = n^{n^{1/8}} \cdot (4n^{3/4} - 4)^{n-n^{1/8}} \cdot (4n^{3/4})^{n^{1/8}}$$

coding $(s, p, r)$ with $s = \sum_{i<n^{1/8}} s_i n^i$, $s_i < n$, and $p < (4n^{3/4} - 4)^{n-n^{1/8}}$ and $r < (4n^{3/4})^{n^{1/8}}$ to the following pair $(\rho_1, \rho_2)$ of restrictions: the variables $x_{s_i+1}, i < n^{1/8}$, are set according $r$ (in particular, these variables might be left unassigned by $\rho_1, \rho_2$); the number $p$ can be used to determine the value pair of $\rho_1$ and $\rho_2$ on every other variable such that not both are ‘unassigned’.

By Lemma 3.2 (ii), (iii), with probability $\geq 3\epsilon 1 - 2/n^{2k}$ we have that $\rho_1, \rho_2$ leave at least $n^{1/8}$ variables unassigned and simplify all CNFs and DNFs at the bottom: all these CNFs and DNFs do not depend on $> b$ variables, and thus are ($\text{PV}_1$-provably) equivalent to both CNFs and DNFs of size $\leq (b+1)2^b + 1$. For $\epsilon$ chosen small enough, Proposition 2.10 (ii) implies that such restrictions $\rho_1, \rho_2$ exist.

In case $d = 2$ we get a contradiction assuming $n$ is large enough so that $n^{1/8} > b$: if $C'_n$ computed parity, then it depends on all its variables.

In case $d > 2$, the circuit $C'_n|_{\rho_1 \rho_2}$ is equivalent to a circuit with $\geq n^{1/8}$ variables, depth $d - 1$ and size $\leq ((b+1)2^b + 1)n^{2k}$. If $C'_n$ computed parity on $2^n$ then from $C'_n|_{\rho_1 \rho_2}$ we get a circuit $C'_n'$ computing parity or its negation on $2^n$, $n' := [n^{1/8}]$. This circuit has depth $d - 1$ and size $(n')^{k'}$ for suitably large $k'$. Arguing by induction on $d \geq 2$, we can assume to have already refuted the existence of such a circuit. \(\square\)
Remark 3.8. We point out which steps in the proof presented rely on sWPHP(PV). In the proof of Lemma 3.5 it is the use of Lemma 3.2 (iii) in the verification of (14). Theorem 3.7 uses the union bound Lemma 3.2 (ii) to bound the probability that all bottom level DNFs simplify. Note that the frequent uses of the first statement of this lemma do not require sWPHP(PV). Lemma 3.2 (iii) is used to argue that restrictions are good with probability \(3\epsilon 1-2/n^2\), and then Proposition 2.10 (ii) is used to infer that good restrictions actually exist.

3.3 Razborov and Smolensky’s lower bound for \(\text{AC}^0[p]\) circuits

Let \(d, p \in \mathbb{N}, p > 0\). An \(\text{AC}^0_d[p]\)-circuit is defined like an \(\text{AC}^0_d\)-circuit but we additionally allow unbounded fan-in gates labeled \(\text{MOD}_p\); such a gate returns 1 or 0 depending on whether it receives a number of ones divisible by \(p\) or not. Recall that, by the size of a circuit we mean the number of its inner gates.

In a first step (Theorem 3.9), for prime \(p\), we want to approximate a given \(\text{AC}^0_d[p]\) circuit by a low degree polynomial over the finite field \(\mathbb{F}_p\). Unfortunately, the sequence of coefficients coding such a polynomial can be infeasible. For this reason, we represent polynomials by arithmetical \(\mathbb{F}_p\)-circuits: these have unbounded fan-in multiplication and addition gates labeled \(\times\) and \(+\) and input gates labeled by variables or constants from \(\mathbb{F}_p\). Instead of the degree of the polynomial computed we use an easily computable upper bound: the syntactic degree of an arithmetical \(\mathbb{F}_p\)-circuit (with one output) is the number it computes (in the obvious sense) when we replace \(\mathbb{F}_p\)-constants by 0, variables by 1, + by max, and \(\times\) by +.

Recall that the sharply bounded collection scheme \(\text{BB}(\Pi^b_1)\) contains

\[\forall i \leq |x| \exists y \leq z \varphi(i, y, \bar{x}) \rightarrow \exists w \forall i \leq |x| \varphi(i, (w)_i, \bar{x})\]

for all \(\varphi \in \Pi^b_1\); here, \((w)_i\) is some standard sequence coding (cf. [32, Section 5.4]).

Theorem 3.9 (Low-degree approximation). For all \(d, p \in \mathbb{N}\) with \(p\) prime the theory

\[\text{S}^1_2 + \text{sWPHP(PV)} + \text{BB}(\Pi^b_1)\]

proves: for \(\ell \in \text{LogLog and } n, s, \epsilon^{-1} \in \text{Log and every } \text{AC}^0_d[p]\)-circuit \(C\) of size \(\leq s\) with \(n\) variables, there is an arithmetical \(\mathbb{F}_p\)-circuit \(P\) of syntactic degree \(\leq ((p-1)\ell)^d\) such that

\[\Pr_{x \leq 2^n}[P(x) \neq C(x)] \leq 0 s/2^\ell + \epsilon.\]

Proof. For a gate \(g\) of \(C\) let \(C_g\) be the subcircuit with output gate \(g\). We prove in \(\text{APC}_1\):
**Claim 3.10.** Let \( g \) be an inner gate of \( C \) and let \( g_1, \ldots, g_m \) list the gates wired into \( g \). Then there exists an arithmetical \( \mathbb{F}_p \)-circuit \( P_g \) with variables \( X_1, \ldots, X_m \) and syntactic degree \( \leq (p-1)\ell \) such that

\[
\Pr_{x < 2^n} \left[ x \in \text{Error}_g \right] \leq 1/2^\ell + \epsilon
\]

where \( \text{Error}_g := \{ x < 2^n \mid P_g(C_{g_1}(x), \ldots, C_{g_m}(x)) \neq C_g(x) \} \). 

If \( g \) is labeled \( MOD_p \), then set \( P_g := 1 - (\sum_{i<m} X_i)^{p-1} \), and, if \( g \) is labeled \( \neg \) (and \( m = 1 \)), then set \( P_g := 1 - X_1 \). Note \( \text{Error}_g = \emptyset \) in both cases. The \( \wedge \)-case being dual, the case that \( g \) is labeled \( \vee \) is the only interesting one.

Observe first that \( \Pr_{S \subseteq m} \left[ \sum_{i \in S} \eta_i = 0 \mod p \right] \leq 1/2 \) for every fixed \( 0 < y < 2^m \), where we write \( y_i := \text{bit}(i, y) \). This implies

\[
\Pr_{x < 2^n \atop S_0, \ldots, S_{\ell-1} \subseteq m} \left[ C_g(x) \neq P_{\bar{S}}(C_{g_1}(x), \ldots, C_{g_m}(x)) \right] \leq 1/2^\ell,
\]

where \( P_{\bar{S}} := 1 - \prod_{i<\ell} (1 - (\sum_{j \in S_i} X_j)^{p-1}) \).

A formally precise notation would replace the index \( S_0, \ldots, S_{\ell-1} \subseteq m \) by \( s < 2^m \cdot \ell \) and \( S_i \), in the event description, should be a suitable PV-term \( t(s,i) \). By Lemma 3.2 (iv) we can fix \( S_0, \ldots, S_{\ell-1} \subseteq m \) such that (16) holds with \( P_g := P_{\bar{S}} \).

We intend to define \( P \) by replacing every inner gate \( g \) of \( C \) by \( P_g \). To do so we need the sequence \((P_g)_g\) where \( g \) ranges over the inner gates of \( C \). It is not obvious that this sequence exists because their defining property is the unbounded \( \exists \Pi_2 \)-formula (16). Theorem 2.9 allows to bring the quantifier complexity down to \( \Pi_2^0 \) as follows.

First choose \( s_g \) such that \( s_g \approx \epsilon \text{Error}_g \) and by Claim 3.10 and Proposition 2.10 (ii)

\[
s_g \leq (1/2^\ell + 3\epsilon) \cdot 2^n.
\]

Theorem 2.9 additionally gives a number \( v_g \) and circuits \( G_g, H_g \) such that

\[
\forall z < v_g \cdot (s_g + \epsilon \cdot 2^n) \left( G_g(z) \in v_g \times \text{Error}_g \right)
\]

\[
\wedge \forall z \in v_g \times \text{Error}_g \left( H_g(z) < v_g \cdot (s_g + \epsilon \cdot 2^n) \wedge G_g(H_g(z)) = z \right).
\]

Thus, \( \text{APC}_1 \) proves that for every \( g \) there exists a (code of a) tuple \( \langle P_g, s_g, v_g, G_g, H_g \rangle \) such that (17) and (18) hold. By Parikh’s theorem [45] (see [9, Theorem 1.2.7.1]) the code of such a tuple can be bounded by a suitable term \( t(C) \). Now, \( \Pi_2^0 \)-collection gives (a code of) a sequence \((\langle P_g, s_g, v_g, G_g, H_g \rangle)_g\) such that (17) and (18) and hence also

\[
\Pr_{x < 2^n} [x \in \text{Error}_g] \leq 1/2^\ell + 4\epsilon.
\]

hold for all \( g \). Given this sequence define \( P \) by replacing each inner gate \( g \) of \( C \) by \( P_g \). By induction, \( P \) has syntactical degree \( \leq ((p-1)\ell)^d \). Also by induction one sees that if
\( P(x) \neq C(x) \) then there exists \( g \) (which is ‘first’ such that the computations differ and hence) such that \( x \in \text{Error}_g \). Applying Lemma 3.2 (ii) we conclude \( \Pr_{x<2^n}[P(x) \neq C(x)] \) is \(<_\epsilon s \cdot (1/2^\ell + 4\epsilon)\), so \(<_0 s \cdot (1/2^\ell + 4\epsilon) + 2\epsilon \) by Lemma 3.2 (i). As \( \epsilon \) was arbitrary with inverse in \( \text{Log} \) and \( s \in \text{Log} \), the theorem follows.

**Remark 3.11.** The above theorem holds true more generally for \( p \in \text{Log} \) instead only for standard primes \( p \in \mathbb{N} \). Jeřábek [27, Section 4.3] formalized basic properties of finite fields in bounded arithmetic, and shows in particular, that, for \( p \in \text{Log} \) prime, \( \text{PV}_1 \) can construct \( \mathbb{F}_p \) and prove \( a^{p-1} = 1 \) for \( a \in \mathbb{F}_p \setminus \{0\} \) [27, Lemma 4.3.11].

To derive an \( \text{AC}^0[p] \) lower bound, one usually proceeds further by showing that any polynomial approximating \( \text{MOD}_q \) with probability \( \geq 3/4 \) must have degree \( \Omega(n^{1/2}) \). The simplest proof of this compares the number of all functions on \( n \) variables to the number of low-degree polynomials. As this argument is infeasible, we reproduce it on functions with only \( \log^{O(1)} n \) arguments. This results in a weaker degree lower bound which, however, still suffices for an \( \text{AC}^0[p] \) lower bound.

The *degree* of an arithmetical \( \mathbb{F}_p \)-circuit is the degree of the polynomial it computes.

**Theorem 3.12 (Degree lower bound).** For any \( d \in \mathbb{N} \) and primes \( p \neq q \), there is \( n_0 \in \mathbb{N} \) such that \( \text{APC}_1 \) proves: if \( n_0 < 2^{\log^{3d} n} \), \( \epsilon^{-1} \in \text{Log} \), then every arithmetical \( \mathbb{F}_p \)-circuit \( P \) with \( n \) variables such that

\[
\Pr_{x<2^n}[P(x) \neq \text{MOD}_q(x_1, \ldots, x_n)] \leq \epsilon 1/(4q)
\]

has degree bigger than \( \log^d n \); here, \( x_i := \text{bit}(i-1, x) \) for all \( 1 \leq i \leq n \).

**Proof.** Assume for contradiction that \( P \) is an arithmetical \( \mathbb{F}_p \)-circuit of degree \( \leq \log^d n \) which differs from \( \text{MOD}_q \) with probability \( \leq \epsilon 1/(4q) \). We consider \( P \) as an arithmetical \( \mathbb{F}_{p^{q-1}} \)-circuit. This (constant size) field contains a \( q \)-th root of unity \( \omega \neq 1 \).

Using the substitution \( y = \frac{x-1}{\omega-1} \) (which maps \( \omega \mapsto 1 \) and \( 1 \mapsto 0 \)) we can construct arithmetical \( \mathbb{F}_{p^{q-1}} \)-circuits \( P_i(x_1, \ldots, x_{n-q}) \), \( i < q \), of degree \( \leq \log^d n \) such that \( P_i(x) = 1 \) if \( \prod_{j=1}^{n-q} x_j = \omega^i \) and \( P_i(x) = 0 \) otherwise, for all except \( \leq \epsilon 1/(4q) \) many \( x \in \{\omega, 1\}^n \). More precisely, \( x \in \{\omega, 1\}^n \) should read \( y < 2^n \), where each \( y \) codes the tuple \( x \), and \( x_j \) abbreviates a \( \text{PV} \)-term denoting its \( j \)-th component.

The circuit

\[
P'(x_1, \ldots, x_{n-q}) := \sum_{i<q} P_i \cdot \omega^i
\]

then has degree \( \leq \log^d n \) and satisfies

\[
\Pr_{x \in \{\omega, 1\}^{n-q}}[P'(x) \neq \prod_{i=1}^{n-q} x_i] \leq q \epsilon 1/4,
\]

by \( (q-1) \) applications of the first statement of Lemma 3.2 (ii).
Let  
\[ m := \log^{3d} n. \]

Rewrite the above event as a set of pairs \((x, a) \in \{\omega, 1\}^m \times \{\omega, 1\}^{n-m}\) and apply Lemma 3.2 (iv) to fix \(a \in \{\omega, 1\}^{n-m}\) such that

\[
\Pr_{x \in \{\omega, 1\}^m}[X] \leq q \epsilon 1/4 + 9q \epsilon,
\]

where \(X := \{x \in \{\omega, 1\}^m \mid P'(x, a) \neq \prod_{i=1}^m x_i \prod_{i=1}^{n-m} a_i\}\).

By our assumption that \(2^m \in \log\), so the set \(X\) can be counted precisely in \(\mathsf{PV}_1\) (cf. Section 2.3). In particular, \(\text{Card}(X) \leq 1/3 \cdot 2^m\) if \(\epsilon\) is sufficiently small. Define the circuit

\[
P''(x) := P'(x, a) \cdot (\prod_{i=1}^{n-m} a_i)^{-1}.
\]

Now, consider an arbitrary function \(f : \{\omega, 1\}^m \to \mathbb{F}_{p^q-1}\). For \(a, b \in \{1, \omega\}\) observe

\[
\frac{2ab - (1 + \omega)(a + b) + 1 + \omega^2}{(1 - \omega)^2} = \begin{cases} 
1 & \text{if } a = b \\
0 & \text{else}.
\end{cases}
\]

We can thus express \(f\) as

\[
f(x) = \sum_{b \in \{\omega, 1\}^m} f(b) \cdot \prod_{i=1}^m \frac{2x_i b_i - (1 + \omega)(x_i + b_i) + 1 + \omega^2}{(1 - \omega)^2} = \sum_{b \in \{\omega, 1\}^m} f(b) \cdot \prod_{i=1}^m \frac{x_i t_{i,1} + t_{i,2}}{(1 - \omega)^2}
\]

where \(t_{i,1} := 2b_i - (1 + \omega)\) and \(t_{i,2} := -(1 + \omega)b_i + 1 + \omega^2\). For \(x \notin X\) we know \(P''(x) = \prod_{i=1}^m x_i\), and thus can write

\[
\prod_{i=1}^m (x_i t_{i,1} + t_{i,2}) = \sum_{T \subseteq [m]} \prod_{i \in T} x_i \cdot \prod_{i \in [m] \setminus T} t_{i,2} + P''(x) \cdot \sum_{T \subseteq [m]} \prod_{i \in T} t_{i,1} \prod_{i \in [m] \setminus T} t_{i,2} x_i^{q-1},
\]

where we use that \(x_i^{q-1} = 1\). Since

\[
x_i^{q-1} = \sum_{z \in \{\omega, 1\}} z^{q-1} \frac{2x_iz - (1 + \omega)(x_i + z) + 1 + \omega^2}{(1 - \omega)^2},
\]

we conclude that \(f\) is computed by a polynomial of degree \(\lceil \frac{m}{2} \rceil + m^{1/3} + 1\). Note that the circuit \(P''(x)\) can be expanded to the sum of \(\leq 2^m \in \log\) monomials so the polynomial representing \(f\) can be coded by the sequence of its coefficients. By Proposition 2.4, the number of such polynomials is

\[
\lesssim_0 (p^q-1)^{\sum_{i=0}^{\lceil \frac{m}{2} \rceil + m^{1/3} + 1} \binom{m}{i}} < (p^q-1)^{(5/9)2^m}
\]

while the number of all functions \(f : \{1, \omega\}^m \setminus X \to \mathbb{F}_{p^q-1}\) is \(\gg_0 (p^q-1)^{(2/3)2^m}\). This contradicts Proposition 2.10 (ii).
Corollary 3.13. For any \( d \in \mathbb{N} \) and primes \( p \neq q \), there is \( n_0 \in \mathbb{N} \) such that \( \text{APC}_1 \) proves: if \( n_0 < 2^{\log^3 n} \in \text{Log} \), then for every size \( \leq n^{\log n} \) \( \text{AC}_0[p] \)-circuit \( C \) with \( n \) variables there is \( x < 2^n \) such that \( C(x) \neq \text{MOD}_q(x_1, \ldots, x_n) \); here, \( x_i := \text{bit}(i-1, x) \) for all \( 1 \leq i \leq n \).

Proof. It suffices to give the proof in the theory of Theorem 3.9. Indeed, by [26, Corollary 4.12] this theory is \( \Sigma^b_2 \)-conservative over \( S^1_2 + \text{sWPHP}(\text{PV}) \) which in turn is \( \Sigma^b_1 \)-conservative over \( \text{APC}_1 \) by Theorem 2.7. In particular, we are free to use Theorem 3.9. We apply this theorem to a given \( \text{AC}_0[p] \)-circuit \( C \) of size \( s \in \text{Log} \) with \( \epsilon := 1/(8q) \) and \( \ell := \lceil \log(8qs) \rceil \in \text{LogLog} \). This yields an arithmetical \( \mathbb{F}_p \)-circuit \( P \) of syntactical degree \( \leq (\ell \cdot (p-1)) \) such that

\[
\Pr_{x < 2^n} [P(x) \neq C(x)] \leq 1/(4q).
\]

If \( C \) computes \( \text{MOD}_q \), then \((\lceil \log(8qs) \rceil \cdot (p-1))^d \geq \log^3 n \) by Theorem 3.12, and hence \( s > n^{\log n} \) as claimed. \( \Box \)

Remark 3.14. We point out which steps in the proof presented rely on \( \text{sWPHP}(\text{PV}) \). The proof of Theorem 3.9 heavily relies on the \( \text{sWPHP}(\text{PV}) \), namely first in the averaging argument Lemma 3.2 (iv) in the proof of Claim 3.10, then in the use of Theorem 2.9 preparing the application of the collection scheme, and then in the final union bound Lemma 3.2 (ii). In the proof of Theorem 3.12 we have the averaging argument Lemma 3.2 (iv) in the construction of the polynomial \( P'' \) approximating the iterated product. The final contradiction relies on Proposition 2.10 (ii).

3.4 Razborov’s lower bound for monotone circuits

We view numbers \( G < 2\binom{n}{2} \) as graphs on \([0, n)\) in the natural way. By a monotone circuit we mean a circuit without \( \neg \)-gates and all inner gates of fan-in 2. If it has \( \binom{n}{2} \) variables we write them as \( x_{\{i,j\}} \) for \( i, j < n, i \neq j \), indicating presence of an edge between \( i \) and \( j \) in an input graph \( G \).

Theorem 3.15. There are \( \epsilon > 0 \) and \( n_0 \in \mathbb{N} \) such that \( \text{APC}_1 \) proves: for all \( n > n_0 \) and \( 2 \leq k \leq n^{1/4} \) such that \( n^k \in \text{Log} \), no monotone circuit of size \( n^{\ell k} \) with \( \binom{n}{2} \) variables accepts exactly the \( n \)-vertex graphs containing a clique of size \( k \).

Proof. We follow the presentation in [5, Section 4.2] (cf. also [3]). Let \( C \) be a monotone circuit with \( \binom{n}{2} \) variables and size \( s \) and set

\[
\ell := \sqrt{k}, \quad p := \ell \cdot \lceil \log n \rceil, \quad m := (p-1)\ell \cdot \ell!.
\]

Observe that all these numbers are in \( \text{Log} \). For \( \tilde{m} \in \text{Log} \) we naturally code length \( \tilde{m} \) sequences \( \tilde{X} = (X_0, \ldots, X_{\tilde{m}-1}) \) of size \( \leq \ell \) subsets \( X_i \subseteq n \) by a number \( < n^{\ell \tilde{m}} \). In the following we understand that \( \tilde{X}, \tilde{Y}, \ldots \) range over such sequences of different lengths.
We aim to approximate $C$ by an “approximator circuit” $C[\tilde{X}] : 2^{(\tilde{n}/2)} \to 2$ where $\tilde{X}$ has length $< m$: it maps $G < 2^{(\tilde{n}/2)}$ to 1 or 0 depending on whether there is $i < m$ such that $G$ has a clique on $X_i$. The approximation is measured with respect to “test graphs”: the “positive” ones are the graphs $P_i$, for $i < \binom{n}{k}$, containing a clique on the $i$-th size $k$ subset of $n$ and no other edges; the “negative” ones are the graphs $N_c$, for $c < (k - 1)^n$, having an edge between $j$ and $j'$ if and only if $c_j \neq c_{j'}$ where we write $c = \sum_{i<n} c_i (k - 1)^i$ with $c_i < k - 1$.

Claim 3.16 (Sunflower lemma). If $\tilde{X}$, say, of length $\tilde{m}$ contains $\geq m$ distinct sets, then it contains a sunflower, i.e. a set $F \subseteq \tilde{m}$ of $p$ pairwise distinct indices such that for some center $X \subseteq n$ we have $X_j \neq X_j \cap X_j' = X$ for all $j, j' \in F, j \neq j'$.

The usual proof (e.g. [5, Lemma 4.1]) formalizes without change in $\PV_1$ because all sets appearing in it have bounds in $\Log$, so $\PV_1$ can count them precisely (recall Section 2.3).

There is a function $plucking \in \PV$ which provably in $\PV_1$ maps $\tilde{X}$ to itself if it contains $< m$ many pairwise distinct sets, and otherwise to a sequence

$$\langle \langle F^1, \tilde{X}^1 \rangle, \ldots, \langle F^u, \tilde{X}^u \rangle \rangle$$

for some $u \geq 1$ such that we have for all $1 \leq i < u$:

- $\tilde{X}^i$ contains at least $m$ pairwise distinct sets,
- $F^i$ is a sunflower in $\tilde{X}^{i-1}$ (we understand $\tilde{X}^0 := \tilde{X}$), say, with center $X$,
- $\tilde{X}^i$ is obtained from $\tilde{X}^{i-1}$ by replacing entries $X_{j}^{i-1}$ with $j \in F^i$ by $X$,
- $\tilde{X}^u$ contains $< m$ many pairwise distinct sets.

The function $plucked$ takes $\tilde{X}$ to $\tilde{Z}$ obtained from $\tilde{X}^u$ above by deleting repetitions, i.e. deleting any entry equal to an earlier one.

Given $\tilde{X}, \tilde{Y}$ of lengths $m', m'' < m$ respectively, we define

$$\tilde{X} \sqcup \tilde{Y} := plucked(\tilde{Z})$$

where $\tilde{Z}$ is the concatenation of $\tilde{X}$ and $\tilde{Y}$, that is, is the length $m' + m''$ sequence with $Z_i = X_i$ for $i < m'$ and $Z_i = Y_i$ for $m' \leq i < m''$. Similarly define

$$\tilde{X} \sqcap \tilde{Y} := plucked(\tilde{Z})$$

where $\tilde{Z}$ is obtained from $\tilde{X} \times \tilde{Y}$ by deleting all entries of size $> \ell$ where “size” is $\Card$ (cf. Section 2.3). The sequence $\tilde{X} \times \tilde{Y}$ is defined such that $C[\tilde{X}] \wedge C[\tilde{Y}] = C[\tilde{X} \times \tilde{Y}]$, namely as the length $m' \cdot m'' = m' \times m''$ sequence with $(i, j)$-th entry $X_i \cup Y_j$.

The following claim states that $\sqcup, \sqcap$ approximate $\vee, \wedge$ with respect to positive and negative test graphs. Note that positive test graphs form a probability space in $\Log$, so events can be counted precisely using $\Card$:
Claim 3.17. Let $\mathbf{X}, \mathbf{Y}$ have lengths $m', m'' < m$ respectively and let $\gamma^{-1} \in \text{Log}$. Then

\[
\text{Card}\left(\left\{ x < \binom{n}{k} \mid C[\mathbf{X} \cup \mathbf{Y}](P_x) < (C[\mathbf{X}] \lor C[\mathbf{Y}])(P_x) \right\}\right) / \binom{n}{k} = 0 \quad \text{(20)}
\]

\[
\text{Card}\left(\left\{ x < \binom{n}{k} \mid C[\mathbf{X} \cap \mathbf{Y}](P_x) < (C[\mathbf{X}] \land C[\mathbf{Y}])(P_x) \right\}\right) / \binom{n}{k} \leq m^2 \cdot (k/n)^{\ell+1} \quad \text{(21)}
\]

\[
\Pr_{c<\binom{k-1}{n}} \left[ C[\mathbf{X} \cup \mathbf{Y}](N_c) > (C[\mathbf{X}] \lor C[\mathbf{Y}])(N_c) \right] \leq \gamma \cdot m \cdot 1/2^p \quad \text{(22)}
\]

\[
\Pr_{c<\binom{k-1}{n}} \left[ C[\mathbf{X} \cap \mathbf{Y}](N_c) > (C[\mathbf{X}] \land C[\mathbf{Y}])(N_c) \right] \leq \gamma \cdot m^2 \cdot 1/2^p \quad \text{(23)}
\]

The event in (20) is empty since $C[\text{plucked}(\mathbf{Z})](G) \geq C[\mathbf{Z}](G)$ for all $\mathbf{Z}$ and $G < 2^{\binom{n}{2}}$. For the same reason, for every $x < \binom{n}{k}$ in the event in (21) there are $i < m', j < m''$ such that $X_i \cup Y_j$ has size $\ell$ and is contained in the $x$-th size $k$ subset of $n$; for every such $i, j$ this has probability $\leq \binom{n-\ell-1}{k-\ell-1} / \binom{n}{k} \leq (k/n)^{\ell+1}$ and (21) follows from the union bound.

To see (22) let $\text{plucking}(\mathbf{Z}) = \langle \langle F^1, \mathbf{Z}^1 \rangle, \ldots, \langle F^u, \mathbf{Z}^u \rangle \rangle$ for $\mathbf{Z}$ the concatenation of $\mathbf{X}$ and $\mathbf{Y}$, and note $u < m$. If $c < (k-1)^n$ is such that $C[\mathbf{X} \cup \mathbf{Y}](N_c) > (C[\mathbf{X}] \lor C[\mathbf{Y}])(N_c)$ then there is $1 \leq i \leq u$ such that $C[\mathbf{Z}^{i-1}](N_c) = 0$ and $C[\mathbf{Z}^i](N_c) = 1$ (again $\mathbf{Z}^0 := \mathbf{Z}$). Then $c$, viewed as a function $i \mapsto c_i$ from $n$ to $k-1$, is injective on the center $X$ of the sunflower $F^i$ but contains a collision on each of the $p$ many petals $X_j \setminus X, j \in F^i$. Since the petals are disjoint such collisions happen with probability $\leq \gamma_0 \left( \left( \binom{\ell}{2}/(k-1) \right)^p < 1/2^p \right.$.

We leave it to the reader to witness $\leq \gamma_0$ by a circuit: note $(k-1)^{\ell} \in \text{Log}$, so given a petal $\text{PV}_1$ can list all $\leq \left( \binom{\ell}{2}/(k-1) \right) \cdot (k-1)^{\ell}$ many functions with a collision on it. Now (22) follows from Lemma 3.2 (ii).

To see (23) let $\mathbf{X} \cap \mathbf{Y} = \text{plucked}(\mathbf{Z})$ for $\mathbf{Z}$ obtained from $\mathbf{X} \times \mathbf{Y}$ as described. Observe $C[\mathbf{Z}](G) \leq C[\mathbf{X} \times \mathbf{Y}](G)$ for all $G < 2^{\binom{n}{2}}$, so $C[\text{plucked}(\mathbf{Z})](N_c) > C[\mathbf{Z}](N_c)$ is the event under consideration. Its probability is estimated as above, now with $u \leq m^2$.

Claim 3.18. Let $\gamma^{-1} \in \text{Log}$. There is a length $< m$ sequence $\mathbf{X}$ such that

\[
\text{Card}\left(\left\{ x < \binom{n}{k} \mid C[\mathbf{X}](P_x) < (C[\mathbf{X}](P_x) \right\}\right) / \binom{n}{k} \leq s \cdot m^2 \cdot (k/n)^{\ell+1}, \quad \text{(24)}
\]

\[
\Pr_{c<\binom{k-1}{n}} \left[ C[\mathbf{X}](N_c) > C(N_c) \right] \leq \gamma \cdot s \cdot m^2 \cdot 1/2^p. \quad \text{(25)}
\]

There is a function in $\text{PV}$ that maps every gate $g$ of $C$ to a length $< m$ sequence $\mathbf{X}^g$ such that $\text{PV}_1$ proves:

- If $g$ is labeled with a variable $x_{i,j}$, then $\mathbf{X}^g$ is the length 1 sequence $\langle \{i, j\} \rangle$;
- If $g$ is labeled 1 or 0, then $\mathbf{X}^g$ is $\langle \emptyset \rangle$ or the empty sequence respectively;
- If $g$ is labeled $\lor$ or $\land$, then $\mathbf{X}^g$ is obtained by applying $\lor$ or $\land$ to the sequences computed for the gates wired into $g$.
We verify the claim for $\vec{X} := \vec{X}^g$ for the output gate $g$ of $C$. To see (24) note for any $x$ in the event there is a first gate $g_x$ of $C$ such that $C[\vec{X}^{g_x}](P_x) = 0$ while in $C$ gate $g_x$ computes 1 on $P_x$; here we refer to an enumeration of the gates of $C$ such that any gate appears before the gates it is wired into. Since $C[\vec{X}^g]$ agrees with $g$ if $g$ is an input gate, $g_x$ is an inner gate. Thus $x$ is in the event of (20) or (21) with $\vec{X}, \vec{Y}$ denoting the sequences computed for the gates wired into $g_x$. Hence, (24) follows by a union bound.

For (25) we argue analogously, the final union bound being done by Lemma 3.2 (ii) causing the error $\gamma$ for approximate counting. The lemma is applied to the the sequence $(E_g)_g$ of error sets where $g$ runs over the gates of $C$. More precisely, $E_g$ is the event in (22) or (23) for $\vec{X}, \vec{Y}$ the sequences computed for the gates wired into $g$. It is easy to prove the existence of this sequence by $\Sigma_1^b$ length induction whose use is permitted by Theorem 2.7.

Now assume $C$ has size $s \leq n^{\epsilon \cdot \ell}$ and accepts all $P_x$ and rejects all $N_c$. Choosing $\vec{X}$ according to Claim 3.18 we get a contradiction by distinguishing two cases.

First suppose that $\vec{X}$ is the empty sequence, so $C[\vec{X}]$ is identically 0. Then the event in (24) is trivial so the l.h.s. equals 1. Recalling (19) and the assumption $k \leq n^{1/4}$ we have $s m^2 < n^{(\epsilon + 2/3)\ell}$, so the r.h.s is $< n^{(2/3 + \epsilon)\ell - 3\ell/4} < 1$ (assuming $\epsilon$ small enough).

So suppose $\vec{X} = \langle X_1, \ldots \rangle$ is not empty. Then $C[\vec{X}](N_c) = 1$ if $c$ does not have a collision on $X_1$; denote this event by $Y$. Then

$$1/2 \cdot (k - 1)^n \leq \frac{1}{13} y \leq \frac{1}{13} s m^2 \cdot 1/2^p \cdot (k - 1)^n \leq n^{(\epsilon + 2/3)\ell} \cdot n^{-\ell} \cdot (k - 1)^n,$$

where the first $\leq 1/13$ follows from Lemma 3.2 (iii): recall $\text{Card}(X_1) \leq \ell$ and we already noted that a collision has probability $\leq 0 (\ell^2)/(k - 1) \leq 1/2$. Proposition 2.10 (ii) gives

$$1/2 \cdot (k - 1)^n < n^{(\epsilon - 1/3)\ell} \cdot (k - 1)^n + 3/13 \cdot 2^{\ell(k - 1)^n} \leq n^{(\epsilon - 1/3)\ell} + 6/13 \cdot (k - 1)^n,$$

and this is wrong if $\epsilon$ is small enough and $n$ is large enough. 

\[ \square \]

**Remark 3.19.** We point out which steps in the proof presented rely on sWPHP(PV). The proofs of (22), (23) and (25) use the union bound Lemma 3.2 (ii). The final contradiction uses Lemma 3.2 (iii) and Proposition 2.10 (ii).

### 3.5 Probabilistic witnessing

We find it worthwhile to point out explicitly the following complexity theoretic benefit of succinct circuit lower bound proofs in APC$_1$. It is a direct application of Wilkie’s Witnessing Theorem 2.7.

**Proposition 3.20.** Let $k, n_0 \in \mathbb{N}$. If APC$_1$ proves $(n_0 \leq n \rightarrow \text{LB}[C, Q](C, n^k, n, N))$, then there exists a probabilistic polynomial time Turing machine which given $n \geq n_0$ in unary and a circuit $C$ of size $\leq n^k$, outputs with probability at least $2/3$ some $y < 2^n$ such that $C$ does not decide $Q$ on $y$, that is, $C(y) = 1, y \notin Q$ or $C(y) = 0, y \in Q$. 

27
For example, we get:

**Corollary 3.21.** Let $k \geq 2$. There exists $n_0 \in \mathbb{N}$ and $\epsilon > 0$ and a probabilistic polynomial time Turing machine which given $n \geq n_0$ in unary and a monotone circuit $C$ of size $\leq n^{\epsilon \sqrt{k}}$, outputs with probability at least $2/3$ a graph $G$ on $n$ vertices such that $C$ does not decide $k$-CLIQUE on $G$.

In fact, the probabilistic witnessing is definable and provable in $\text{PV}_1$ and $\text{APC}_1$ in appropriate senses. We refer the interested reader to [26, Proposition 1.16].

### 3.6 Razborov and Rudich's natural proof barrier

The definitions of natural properties and pseudorandom generators both require to count the sizes of certain sets quite precisely, namely up to certain inverse polynomial factors. Formalizing these concepts in $\text{APC}_1$ thus requires careful quantification of the error in approximate counting. Cleaner definitions of these concepts can be given in the theory $\text{APC}_1^+$ of Buss et al. [12]: relativize $\text{APC}_1$ to a new binary function symbol $\text{Sz}$, i.e. take $\text{PV}_1(\text{Sz}) + \text{sWPHP}(\text{PV}_1(\text{Sz}))$, and add the axiom

$$n,\epsilon^{-1} \in \text{Log} \wedge C \text{ is a circuit with } n \text{ variables } \rightarrow \{x < 2^n \mid C(x) = 1\} \approx_{\epsilon} \text{Sz}(C, 2^n). \hspace{1cm} (26)$$

Intuitively, $\text{APC}_1^+$ adds to $\text{APC}_1$ approximate cardinalities with error smaller than all inverse polynomial factors simultaneously but does not add any reasoning power. More precisely, the following is [12, Proposition 13]. Its proof builds on Jeřábek’s theory $\text{HARD}^A$ mentioned in Section 2.3.

Let $\Sigma_b^\infty$ denote the set of all bounded $\text{PV}$-formulas.

**Theorem 3.22.** The theory $\text{APC}_1^+$ is $\Sigma_b^\infty$-conservative over $\text{APC}_1$.

For $X \subseteq 2^n$ defined by circuit $C$ we write $\text{Sz}(X)$ for $\text{Sz}(C, 2^n)$.

**Definition 3.23** (in $\text{APC}_1^+$). For circuit definable $X \subseteq 2^n$ set

$$\text{Pr}_{x < t}[x \in X] := \text{Sz}(\{x \in X \mid x < t\})/t.$$  

Of course, approximate probabilities in $\text{APC}_1^+$ and $\text{APC}_1$ are approximately the same:

**Lemma 3.24.** The theory $\text{APC}_1^+$ proves for all $t$, circuit definable $X \subseteq 2^n$ and $0 \leq p, \epsilon, \gamma \leq 1$ with $\gamma^{-1} \in \text{Log}:

(i) if $\text{Pr}_{x < t}[x \in X] \geq p$, then $\text{Pr}_{x < t}[x \in X] \geq p - (2\epsilon + \gamma)$;

(ii) if $\text{Pr}_{x < t}[x \in X] \leq p$, then $\text{Pr}_{x < t}[x \in X] \leq p + (2\epsilon + \gamma)$;

(iii) if $\text{Pr}_{x < t}[x \in X] \geq p$, then $\text{Pr}_{x < t}[x \in X] \geq \gamma p$;

(iv) if $\text{Pr}_{x < t}[x \in X] \leq p$, then $\text{Pr}_{x < t}[x \in X] \leq \gamma p$.  

28
Proof. (i): we only show the first statement. If \( \Pr_{x \leq t}[x \in X] \geq \epsilon p \), then by (26)
\[
\Pr_{x \leq t}^+[x \in X] \cdot t = Sz(\{x \in X \mid x < t\}) \approx_{\gamma/4} \{x \in X \mid x < t\} \geq \epsilon pt.
\]
This implies \( \Pr_{x \leq t}^+[x \in X] \geq p - (2\epsilon + \gamma) \) via Proposition 2.10 (ii):
\[
pt \leq \Pr_{x \leq t}^+[x \in X] \cdot t + (\epsilon + \gamma/4 + \gamma/4) \cdot 2^{|t|} \leq \Pr_{x \leq t}^+[x \in X] \cdot t + (\epsilon + \gamma/2) \cdot 2t.
\]
(ii): again, we only show the first statement. If \( \Pr_{x \leq t}^+[x \in X] \geq p \), then by (26)
\[
\{x \in X \mid x < t\} \approx_{\gamma} Sz(\{x \in X \mid x < t\}) \geq pt,
\]
so \( \{x \in X \mid x < t\} \geq_{\gamma} pt \), i.e. \( \Pr_{x \leq t}[x \in X] \geq_{\gamma} p \).

□

**Definition 3.25** (in APC\(^+_1\)). Let \( s \in \text{Log} \). A circuit \( G \) with \( k \) variables and \( 2k \) outputs is an \( s\)-secure pseudorandom generator if for all circuits \( C \) with \( 2k \) variables and size \( \leq s \):
\[
\left| \Pr_{y \leq 2^k}^+[C(y) = 1] - \Pr_{x \leq 2^k}^+[C(G(x)) = 1] \right| < 1/s.
\]

As Chow [15, Theorem 1] we present Razborov and Rudich’s naturalization barrier namely as one “to proving superquadratic circuit lower bounds” [15, p. 730]. Since approximate counting incurs inverse polynomial errors we use Razborov and Rudich’s largeness parameter \( 2^{-dm} \) instead Chow’s \( 2^{-md} \).

**Theorem 3.26** (Natural proof barrier). For all \( c, d \in \mathbb{N} \) and \( 0 < \delta < 1 \) there is \( k_0 \in \mathbb{N} \) such that APC\(^+\) proves for all \( k \geq k_0 \) with \( k^\delta \in \text{LogLog} \) and \( m := \left\lceil k^{\delta/2} \right\rceil \): if

(Constructivity) \( C \) is a circuit with \( 2^m \) variables and size \( \leq 2^{dm} \),
(Largeness) \( \Pr_{f \leq 2^{2^m}}^+[C(f) = 1] \geq 1/2^{dm} \),
(Usefulness) \( C \) accepts only functions of circuit complexity \( > (c + 4)m^{1+2c/\delta} \), i.e.
\[
\forall f, D, M \ (C(f) = 1 \rightarrow \text{LB}_{tt}(f, D, (c + 4)m^{1+2c/\delta}, m, M))
\]
then \( 2^{k^\delta} \)-secure pseudorandom generators with \( k \) variables and size \( \leq ck^c \) do not exist.

Proof. Argue in APC\(^+\). Assume \( G \) is a size \( \leq ck^c \) circuit with \( k \) variables and \( 2k \) outputs. Assuming there is \( C \) as stated we show \( G \) is not \( 2^{k^\delta} \)-pseudorandom for large enough \( k \).

Let \( G' : 2^k \times 2 \rightarrow 2^k \) be a size \( \leq 4k + ck^c \) circuit that maps \( \langle x, 0 \rangle \) and \( \langle x, 1 \rangle \) respectively to the first and the last \( k \) bits of \( G(x) \). For \( b < 2 \) we write \( G^b(x) := G'(\langle x, b \rangle) \). For \( y < 2^m \) write \( y_i \) for \( \text{bit}(i, y) \). Consider a circuit \( G'' : 2^k \times 2^m \rightarrow 2 \) that maps \( \langle x, y \rangle \) to
\[
\text{bit}(0, G'^{y_{m-1}} \circ \cdots \circ G'^0(x)).
\]
Such a circuit is constructed using $m$ copies of $G'$ so has size $\leq (c+4)m^{1+2c/\delta}$. Hardwiring some fixed $x < 2^k$ into $G''$ computes the function $y \mapsto G''(\langle x, y \rangle)$. Let $G_x < 2^{2m}$ be its truth table, i.e. $\text{bit}(y, G_x) = G''(\langle x, y \rangle)$ for all $y < 2^m$. By (Usefulness) $C(G_x) = 0$, so

$$\Pr^+_{t < 2^m}[C(f) = 1] - \Pr^+_{x < 2^k}[C(G_x) = 1] \geq 1/2^{dm}. \quad (27)$$

by (Largeness). Consider now the binary tree $T$ of height $m$. List its internal nodes $t_1, \ldots, t_{2^m-1}$ so that $i < j$ whenever $t_i$ is a child of $t_j$. Identify its leaves with $[0, 2^m)$. For $i < 2^m$ let $T_i$ be the union of subtrees of $T$ whose nodes are $\{t_1, \ldots, t_i\}$ along with all the leaves. For a leaf $y < 2^m$, let $r_i(y)$ be the root of the subtree in $T_i$ containing $y$, and let $h(i, y)$ denote its height. In particular, $r_0(y) = y$ and $h(0, y) = 0$.

Let $a$ range over $[0, 2^{k2^{m+1}})$ and view it as an assignment mapping nodes $t$ of $T$ to $a(t) < 2^k$. Given such $a$ and $i < 2^m$ define for $y < 2^m$

$$G^a_i(y) := \text{bit}(0, G^{y_{m-1}} \circ \cdots \circ G^{y_{m-h(i, y)}}(a(r_i(y))). \quad (28)$$

We blurr the distinction between the function $G^a_i$ and its truth table, and write

$$p_i := \Pr^+_a[C(G^a_i) = 1]$$

for $i < 2^m$. For $r$ the root of $T$ we have $G^a_{2^m-1}(y) = G''(\langle a(r), y \rangle)$ for all $y < 2^m$, that is, $G^a_{2^m-1} = G_a(r)$. Further, $G^a_0(y) = \text{bit}(0, a(y))$ for all $y < 2^m$. Hence, intuitively, the probabilities $p_i$ and $p_0$ are those in (27) albeit taken over longer strings $a$. More precisely, for any $\gamma^{-1} \in \text{Log}$ Lemma 3.24 (ii) implies $\Pr_a[C(G^a_{2^m-1}) = 1] \geq \gamma p_{2^m-1}$ which, as is easily seen, implies $\Pr_{x < 2^k}[C(G_x) = 1] \geq \gamma p_{2^m-1}$, and hence $\Pr^+_x[C(G_x) = 1] \geq p_{2^m-1} - 3\gamma$ by Lemma 3.24 (i). Similarly, $\Pr^+_f[C(f) = 1] \leq p_0 + 3\gamma$, so by (27)

$$p_0 - p_{2^m-1} \geq 1/2^{dm} - 6\gamma.$$ 

Set $\gamma := 1/(12 \cdot 2^{dm})$ and note the l.h.s. is $\leq \sum_{i < 2^m-1} |p_i - p_{i+1}|$. Hence there is $j < 2^m - 1$ such that $|p_j - p_{j+1}| \geq 1/2^{(d+1)m+1}$. For simplicity assume $p_j \geq p_{j+1}$, so

$$p_j - p_{j+1} \geq 1/2^{(d+1)m+1}. \quad (29)$$

By Lemma 3.24 (ii) the event $C(G^a_{j+1}) = 1$ has probability $\leq \epsilon p_{j+1}$ for any $\epsilon^{-1} \in \text{Log}$. Rewrite this event as a set of pairs $\langle a_0, a_1 \rangle \in 2^k \times 2^k(2^{m+1}-1)$ understanding that $a_0$ determines $a(t_{j+1})$ and $a_1$ determines the rest of $a$. Accordingly write $G^{\langle a_0, a_1 \rangle}_{j+1}$ for $G^a_{j+1}$. Clearly, the rewritten event has probability $\leq \epsilon p_{j+1}$. By Lemma 3.2 (iv)

$$\Pr_{a_0 < 2^k}[C(G^{\langle a_0, a_1 \rangle}_{j+1}) = 1] \leq \epsilon p_{j+1} + 9\epsilon$$

for some $a_1 < 2^{k(2^{m+1}-1)}$. By Lemma 3.24 (i)

$$\Pr^+_{a_0 < 2^k}[C(G^{\langle a_0, a_1 \rangle}_{j+1}) = 1] \leq p_{j+1} + 12\epsilon. \quad (30)$$
Similarly, rewrite the event $C(G_j^{a_j}) = 1$ as a set of pairs $\langle b_0, b_1 \rangle$ with $b_0 < 2^{2k}$ determining $a(t_{j+1}^0)$ and $a(t_{j+1}^1)$ for the children $t_{j+1}^0, t_{j+1}^1$ of $t_{j+1}$ in $T$, and $b_1 < 2^{k(2^{m+1}-2)}$ determining the rest of $a$. Accordingly write $G_j^{(b_0, b_1)}$ for $G_j^{a_j}$. Arguing analogously,

$$\Pr_{b_0 < 2^{2k}}^{+}[C(G_j^{(b_0, b_1)}) = 1] \geq p_j - 12\epsilon,
\tag{31}$$

for some $b_1 < 2^{k(2^{m+1}-2)}$. Setting $\epsilon := 1/(48 \cdot 2^{(d+1)m+1})$ inequalities (29), (30), (31) yield

$$\Pr_{b_0 < 2^{2k}}^{+}[C(G_j^{(b_0, b_1)}) = 1] - \Pr_{a_0 < 2^{k}}^{+}[C(G_j^{a_0, a_1}) = 1] \geq 1/2^{(d+1)m+2}.
\tag{32}$$

Observe that $G_j^{(a_0, a_1)} = G_j^{(G(a_0), a_1')}$, where $a_1' < 2^{k(2^{m+1}-2)}$ is the part of $a_1$ minus the codes of values assigned to $t_{j+1}^0, t_{j+1}^1$. For large enough standard $e \geq d$ the functions $b_0 \mapsto G_j^{(b_0, a_1)}$ and $b_0 \mapsto G_j^{(b_0, b_1)}$ can be computed by circuits of size $\leq 2^{en}$ applying (28) for all leaves $y < 2^m$ above $t_{j+1}^0, t_{j+1}^1$. Thus, the events in (32) are defined by circuits of size $\leq 2^{em+1}$. Since $2^{(d+1)m+2}, 2^{em+1} \leq 2^k$ for large enough $k$, (32) means that $G$ is not $2^{k^\delta}$-pseudorandom. \qed

\section{Propositional proof complexity}

\subsection{Propositional translation}

To fix some notation we briefly recall the propositional simulation of $\text{PV}_1$ by $\text{EF}$ going back to Cook \cite{cook1979}. We choose a particular variant of the propositional translation from the literature and use it to define the propositional tt-formulas (2) from the Introduction. This is for definiteness. The reader’s favorite versions of the definitions of the translation and the tt-formulas can be used for the results in Sections 4.3 and 4.4 provided there are short $\text{EF}$-proofs of equivalence to our versions.

We write propositional formulas in de Morgan language $\land, \lor, \neg, 0, 1$. Fix some standard propositional proof system given by finitely many (axiom schemes and) inference rules; we refer to its proofs as Frege proofs. Extended Frege $\text{EF}$ additionally allows to abbreviate formulas by atoms during the proof. The depth of a Frege proof is the minimal $d$ such that every formula (viewed as a circuit) appearing in it has depth $\leq d$. We refer to \cite[Sections 4.4, 4.5]{Stocker} for definitions.

The propositional translation $[[\varphi]]^{\overline{a}}$ is defined for a $\Sigma^b_0$-formula $\varphi(x_1, \ldots, x_k)$ and length bounds $\overline{n} = (n_1, \ldots, n_k) \in \mathbb{N}^k$ associated to its free variables. Its size is polynomial in $\overline{n}$. It has $n_i$ propositional variables corresponding to $x_i$ plus some auxiliary variables. A tuple $(a_1, \ldots, a_k) \in \prod_{i=1}^k [0, 2^{n_i})$ satisfies $\varphi$ in the standard model if and only if

$$[[\varphi]]^{\overline{a}}[a_1/x_1, \ldots, a_k/x_k]$$
is tautological. Here we allow ourselves some convenient but nonstandard notation: by 
\[a_1/x_1, \ldots, a_k/x_k\] we mean the substitution that for all \(1 \leq i \leq k\) substitutes the Boolean 
constants \(\text{bit}(0, a_i), \ldots, \text{bit}(n_i - 1, a_i)\) for the \(n_i\) many variables corresponding to \(x_i\).

We fix some bounding polynomials \(p_t\) for terms \(t(\bar{x})\) once and for all: \(t(\bar{x})\) takes values of 
length \(\leq p_t(\bar{n})\) on arguments of lengths \(\bar{n}\). We assume that variables \(x\) have the identity as 
bounding polynomial \(p_x\). The translation is defined by induction on the logical complexity 
of \(\varphi\) with straightforward inductive clauses. For example,
\[
\[\exists y < |t(\bar{x})| \varphi(\bar{x}, y)\] := \bigvee_{a < p_t(\bar{n})} [y < |t(\bar{x})| \land \varphi(\bar{x}, y)]^{\bar{n} \cdot |p_t(\bar{n})|} [a/y].
\]

More precisely, we should write \(t(\bar{x}')\) for the subtuple \(\bar{x}'\) of variables from \(\bar{x}\) that actually 
occur in \(t\). We refer to [26, Section 2] for more details.

**Theorem 4.1 (Simulation, Cook 1975).** If \(S_1^2\) proves \(\varphi(\bar{x}) \in \Sigma^0_0\), then there is a polynomial 
time algorithm that, given a tuple \(\bar{n}\) of naturals in unary, computes an \(EF\)-proof of \([[\varphi(\bar{x})]]^{\bar{n}}\).

In [26, Section 2] Jeřábek introduced the propositional proof system \(WF\) and showed 
it simulates \(S_1^2 + \text{sWPHP}(PV)\):

**Theorem 4.2 (Simulation, Jeřábek 2004).** If \(S_1^2 + \text{sWPHP}(PV)\) proves \(\varphi(\bar{x}) \in \Sigma^0_0\), then 
there is a polynomial time algorithm that, given a tuple \(\bar{n}\) of naturals in unary, computes 
a \(WF\)-proof of \([[\varphi(\bar{x})]]^{\bar{n}}\).

**Remark 4.3.** We comment on variants of Theorem 4.1 appearing in the literature and 
motivate our choice [26]. As for some minor differences, the original source [18] uses 
Tseitin’s [62] Extended Resolution and translates only quantifier-free \(PV\)-formulas, [32, 
Section 9.2] uses the QBF system \(G_1\), [7, 10] uses \(EF\) but translate only formulas in Buss’ 
language instead \(PV\). In distinction to [26] the various translations [18, 32, 7, 39] all 
use only a single length bound \(n\) associated to all variables. Such translations are with 
respect to a bounding polynomial that works for all terms appearing in the formula. This 
has the unpleasant property that the translation of a formula can vary when considered 
as a subformula of another. Another unpleasant property is that proofs of analogues of 
Theorem 4.1 in [32] and [7] need to choose a bounding polynomial that works for all 
formulas in the simulated \(PV_1\)-proof, so the translation depends on this proof instead 
only the formula proved – see the statements of [32, Theorem 9.2.5, Corollaries 9.2.6, 
9.2.7]. The statements in [7, Theorem 30] and the underlying lecture notes [10, p.10-6] 
should be rephrased accordingly.

### 4.2 Propositional formalizations of circuit lower bounds

We now consider the translation of \(LB_{tt}[C]\), see (4) in Section 2.2. We use variable \(x\) 
instead \(n\) to avoid a double use of this letter, and substitute for the ‘size’ variable \(s\) a 
\(PV\)-term \(s(N)\). Thus we consider the formula \(LB_{tt}[C](f, C, s(N), x, N)\) with free variables
We omit superscripts in the translations and understand that \( f, C, x, N, y \) have associated length bounds \( 2^n, 2^n, |n|, 2^n, n \) respectively.

We define

\[
\text{tt}[C, f, s(2^n)] := \lfloor \text{LB}_{tt}[C](f, C, s(N), x, N) \rfloor \lfloor 2^{2^n} - 1/N, n/x \rfloor.
\] (34)

Here and below, note this substitutes \( 2^n \) many Boolean constants 1 for the \( 2^n \) variables corresponding to \( N \). Next to some auxiliary variables this formula has \( 2^n \) many variables for the bits of \( f \) and \( 2^n \) many variables for the bits of \( C \). It has size \( 2^{O(n)} \).

Recalling \( \text{LB}^{0}_{tt}[C] \) from (5) in Section 2.2, we see that our formula has the desired form (2) from the Introduction:

\[
\text{tt}[C, f, s(2^n)] = \bigvee_{a<2^n} "C(a) \neq f(a)"
\]

with "\( C(a) \neq f(a) \)" := \( \lfloor \text{LB}^0_{tt}[C](f, C, s(N), x, N, y) \rfloor \lfloor 2^{2^n} - 1/N, n/x, a/y \rfloor \). (35)

Let \( 0 < \epsilon < 1 \) be a rational. It is straightforward to define formulas expressing that a function given by a truth table is not computed by a specific size \( 2^x \) circuit which is computed by a \( PV \)-function. For later use we define these formulas using a copy \( \tilde{f}, \tilde{C}, \tilde{x}, \tilde{N}, \tilde{y} \) of the variables \( f, C, x, N, y \) and substitute a function \( \text{circ}(\tilde{x}, f, \tilde{x}, \tilde{N}) \) for \( \tilde{C} \):

\[
\bigvee_{a<2^m} "\text{circ}(\tilde{x}, \cdot)(a) \neq \tilde{f}(a)"
\] (36)

for \( m \in \mathbb{N} \). As indicated, this formula will have propositional variables for the bits of \( \tilde{f} \) and \( \tilde{x} \) plus auxiliary variables. The definition assumes that the length bounds associated with \( \tilde{f}, \tilde{x}, \tilde{N}, \tilde{y} \) are \( 2^m, 2^m, |m|, m \), and those associated with \( \tilde{x} \) are given by context:

"\( \text{circ}(\tilde{x}, \cdot)(a) \neq \tilde{f}(a) \)" := \( \lfloor \text{LB}^{0}_{tt}(\tilde{f}, \text{circ}(\tilde{x}, f, \tilde{x}, \tilde{N}), \tilde{x}, |\bar{N}|, \tilde{N}, \tilde{y}) \rfloor \lfloor 2^{2^n} - 1/\tilde{N}, m/\tilde{x}, a/\tilde{y} \rfloor \).

To define formulas expressing lower bounds for certain particular problems \( Q \) we substitute the truth table of \( Q \) restricted to \( y < 2^n \) for the variables corresponding to \( f \) in \( \text{tt}[C, f, s(2^n)] \). For example, the formula \( \text{tt}[\text{SAT}, s(2^n)] \) from the Introduction can be defined as \( \text{tt}[C, f, 2^n] \lfloor \text{sat}/f \rfloor \) where \( C \) is the class of all circuits and \( \text{sat} < 2^n \) is the number whose bits give the truth table of \( \text{SAT} \) restricted to \( y < 2^n \). However, in this section we shall reserve the notation \( \text{tt}[C, Q, n^k] \) for translations coming from the succinct formulas \( \text{LB}[C, Q] \) considered below.

**Remark 4.4.** As mentioned in the Introduction, circuit lower bounds yield candidate hard tautologies for \( \text{EF} \) or Frege: for a rational \( 0 < \epsilon < 1 \) one asks whether all infinite subsets of \( \{ \text{tt}[f, 2^en] \lfloor h/f \rfloor | h < 2^{2^n}, n \in \mathbb{N} \} \) are hard for \( \text{EF} \) or Frege.

Recall \( \text{LB}[C, Q] \) and \( \text{LB}^{0}[C, Q] \) from (6) and (7) in Section 2.2. Our translation is not applicable to \( \text{LB}[C, Q] \) because its quantifier complexity is too high even if, and this will be our setting, the defining formula \( Q(y) \) of \( Q \) is \( \Sigma^b_0 \) (i.e. \( Q \in \mathcal{P} \)). Then we can translate
A polynomial time algorithm, we get a Σ₁∃₁In case the existential quantifier.

4.3 Succinct tautologies via witnessing

In case the existential quantifier ∃y<1#N in the formula LB[C, Q] can be witnessed by a polynomial time algorithm, we get a Σ₁∃₁-formula whose propositional translation is a succinct size n^{O(1)} expression of a circuit lower bound:

**Definition 4.5.** Let Q ⊆ N be Σ₀^b-defined. For ternary w ∈ PV define

\[ \text{lb}_w[C, Q, n^k] := \left\lfloor \text{LB}^0[C, Q](C, x^k, x, N, w(C, x, N)) \right\rfloor \left[ 2^n - 1/N, n/x, a/y \right]. \]  

We define \( \text{lb}_{w(,z)}[C, Q, n^k] \) similarly for \( w(C, x, N, z) \) having additional arguments \( z \) which we refer to as parameters of \( w \). The notation is explained only in contexts associating length bounds to \( z \); in particular, when applying a substitution \( \text{lb}_{w(,z)}[C, Q, n^k] \) \( [\bar{a}/\bar{z}] \) for a tuple \( \bar{a} \) from \( N \), we understand that these length bounds are the lengths of the numbers in \( \bar{a} \). Again, we shall omit \( C \) from these notations if it is the set of all circuits.

**Remark 4.6.** Continuing Remark 4.4 a suggestive notation would be \( \text{lb}_{P/poly}[C, Q] \) for the set of formulas \( \text{lb}_{w(,z)}[C, Q, n^k] \) \( [\bar{a}/\bar{z}] \) for all \( w \in PV \) and all tuples \( \bar{a} \) from \( N \). The following definition explains these formulas also for \( Q = SAT \), and the following proposition points out that likely these formulas are tautological for some \( w \). Intuitively, these formulas are even harder than \( \text{tt}[SAT, n^k], n \in N \). We shall, however, not need this notation.

Definition 4.5 can be extended to \( Q \in NP \) as follows. We use standard symbols \( (x)_0, (x)_1 \) from PV giving the first and second component of the ordered pair coded by \( x \).

**Definition 4.7.** Let Q ⊆ N be defined by ∃z<t(y) \( \varphi(z, y) \) where \( t(y) \) is a PV-term and \( \varphi(z, y) \in \Sigma_0^b \). For \( w(C, x, N) \in PV \) define \( \text{lb}_w[C, Q, n^k] \) as

\[
\left\lfloor n = |N| \rightarrow \left( w_1 < 1\#N \land w_0 < t(w_1) \land 
\left( C \text{ is a } C\text{-circuit of size } \leq x^k \rightarrow 
\left( C(w_1) = 0 \land \varphi(w_0, w_1) \right) \lor \left( C(w_1) = 1 \land \neg \varphi(z, w_1) \right) \right) \right) \right\rfloor \left[ 2^n - 1/N, n/x \right],
\]

34
where, for readability, we abbreviated \((w(C, x, N))_0, (w(C, x, N))_1\) by \(w_0, w_1\). The length bound associated to \(z\) is \(p_t(n)\), that is, the bounding polynomial \(p_t\) of \(t\) evaluated at the length bound associated to \(y\).

For \(Q \in \mathbb{P}\) the formula \(\text{LB}[C, Q]\) for \(s = n^k\) is \(\Sigma_1^b\), so in case \(\text{PV}_1\) proves it, Theorem 2.1 implies that there exists \(w \in \text{PV}\) such that \(\text{LB}_w[C, Q, n^k]\) is tautological. This reasoning does not apply for \(Q \in \mathbb{NP}\) because then \(\text{LB}[C, Q] \in \Sigma_2^b\). In this case, provability in \(\text{PV}_1\) implies by the KPT-theorem [40] that the existential quantifier \(\exists y\) is witnessed by a tuple of polynomial time functions \(\bar{w}\) determining a constant round Student-Teacher computation. The corresponding translation gives size \(n^{O(1)}\) formulas \(\text{lb}_w\) weaker than the formulas \(\text{lb}_w\) defined above. We omit their definition and discussion here and refer the interested reader to [48]. Instead, we include a proof that, under some plausible hardness assumptions, the stronger witnessing with a single \(w\) is possible for \(Q = \text{SAT}\). This improves [46, Proposition 4.3] establishing a one round Student-Teacher computation, and, in fact, is a combination of folklore arguments (e.g. [8, 20] contain similar constructions).

**Proposition 4.8.** Assume there exists a one-way permutation, that is, a length preserving bijection \(f : \mathbb{N} \to \mathbb{N}\) such that for all \(k, \ell \in \mathbb{N}\) there is \(n_0 \in \mathbb{N}\) such that for all \(n \geq n_0\) and every size \(\leq n^k\) circuit \(C\) with \(n\) variables and \(n\) outputs we have

\[
\Pr_{x < 2^n}[C(f(x)) = x] < 1/n^\ell.
\]

Assume further that there exists \(h : \mathbb{N} \to \mathbb{N}\) computable in time \(2^{O(n)}\) with hardness \(2^{\Omega(n)}\), that is, there is \(\delta > 0\) such that for all sufficiently large \(n\) and all size \(2^{\delta n}\) circuits \(C\) with \(n\) variables and 1 output we have

\[
\Pr_{x < 2^n}[C(x) = h(x)] < 1/2 + 1/2^{\delta n}.
\]

Then for all \(k \in \mathbb{N}\) there are \(n_0 \in \mathbb{N}\) and a polynomial time algorithm which given \(n \geq n_0\) in unary and a circuit \(C\) of size \(\leq n^k\) computes \(y < 2^n\) such that \(C\) on \(y\) does not decide \(\text{SAT}\), i.e. either \(y \in \text{SAT}, C(y) = 0\) or \(y \notin \text{SAT}, C(y) = 1\).

In other words, there is \(w(C, x, N) \in \text{PV}\) such that \(\text{lb}_w[\text{SAT}, n^k]\) is tautological for sufficiently large \(n\).

**Proof.** Given \(b \in \mathbb{N}\) we can compute in polynomial time a propositional formula \(\alpha_b\) expressing \(f(x) = b\): its variables include \(x_0, \ldots, x_{|b|-1}\); it has exactly one satisfying assignment and this assignment assigns \(\text{bit}(i, f^{-1}(b))\) to \(x_i\). For \(\bar{c} \in \{0, 1\}^{<|b|}\) let \(\alpha_b[\bar{c}]\) be the formula obtained from \(\alpha_b\) by substituting the \(i\)-th bit of \(\bar{c}\) for \(x_{i-1}\).

Let \(C\) be a circuit with \(n\) variables and size \(n^k\). Choose \(n \geq m \geq n^{O(1)}\) such that the formulas \(\alpha_b[\bar{c}]\) for \(b < 2^m\) have size \(\leq n\) and ‘padded versions’ \(\alpha_b^p[\bar{c}]\) have size exactly \(n\); these ‘padded versions’ are logically equivalent formulas with the same variables and computable in time \(n^{O(1)}\).
By the usual self-reducibility argument we find a circuit $D$ which on $b < 2^m$ computes $a := f^{-1}(b)$ if $C$ decides $\text{SAT}$ on all formulas $\alpha^b_i[\text{bit}(0, a), \ldots, \text{bit}(i - 1, a), 1], i < m$. As $m \geq n^{\Omega(1)}$, the size of $D$ is $\leq m^\ell$ for some $\ell \in \mathbb{N}$. Since $f$ is one-way we have, assuming $n$ and hence $m$ is large enough,

$$\Pr_{a < 2^m} [D(f(a)) = a] < 1/m.$$  

Let $D'$ be a circuit that given $a < 2^m$ checks whether $D(f(a)) = a$. This circuit can be chosen of size $m^\ell$ for some $\ell' \in \mathbb{N}$.

There is a constant $c \in \mathbb{N}$ depending only on $\ell'$ such that the Nisan-Wigderson generator [44] $G : 2^{c \log m} \rightarrow 2^m$ satisfies (in fact for all $m^\ell$-size circuits)

$$| \Pr_{a < 2^m} [D'(a) = 1] - \Pr_{s < 2^{c \log m}} [D'(G(s)) = 1] | < 1/m.$$  

It follows that $\Pr_{s < 2^{c \log m}} [D'(G(s)) = 1] < 1$, so there exists $s < 2^{c \log m}$ such that $D(f(G(s))) \neq G(s)$. Hence there exists $i < m$ such that $C$ does not decide $\text{SAT}$ on the size $n$ formula $\alpha^s_i(G(s))[\text{bit}(0, G(s)), \ldots, \text{bit}(i - 1, G(s)), 1]$.  

Note these are $\leq m^c \cdot m \leq n^{c+1}$ many formulas. Our witnessing function $w$ runs $C$ on all of them and outputs the first where $C$ does not decide $\text{SAT}$. This is easy to detect because we know which of our formulas are satisfiable: those with $\text{bit}(i, G(s)) = 1$.  

\section{A general upper bound}

Given our APC$_1$ proofs of circuit lower bounds $\text{LB}[C, Q]$ we would like to conclude that WF admits short proofs of tautologies $\text{lb}_w[C, Q, n^k]$ for some $w$. Unfortunately, this does not follow directly because a priori the APC$_1$-proof yields a witnessing $w$ computable not in deterministic but probabilistic polynomial time (see Section 3.5). We deal with this complication by reformulating the simulation in terms of an implication. We observe that for proving a $\Sigma^b_1$-formula in APC$_1$ the truth table of a single hard function can replace sWPHP($\text{PV}$) in such a way that, in particular, APC$_1$-proofs of $\text{LB}[C, Q]$ for $s = n^k$ translate to short EF proofs of tautologies stating that a truth-table of a single hard function implies $\text{lb}_w[C, Q, n^k]$.

For a tuple $\bar{x} = (x_0, \ldots, x_{k-1})$ of variables we write $|\bar{x}|$ for $\max_{i < k} |x_i|$.

\begin{lemma}
\label{lemma:4.9}
Suppose $S^1_2 + \text{sWPHP(PV)}$ proves $\exists y \varphi(y, \bar{x})$ for $\varphi(y, \bar{x}) \in \Sigma^b_1$. For every rational $0 < \epsilon < 1$ there is $\ell \in \mathbb{N}$ and $g \in \text{PV}$ such that $\text{PV}$ proves

$$|N| \geq |\bar{x}|^\ell \wedge \text{LB}_{\text{tt}}(f, (g(\bar{x}, f, n, N))_0, |N|^\epsilon, n, N) \rightarrow \varphi((g(\bar{x}, f, n, N))_1, \bar{x}).$$  

\end{lemma}

\begin{proof}
It suffices to prove this when $\bar{x}$ is a single variable $x$. It is well-known (see e.g. [29, Theorem 3.1 (i)]) that sWPHP($\text{PV}$) is, over $S^1_2$, equivalent to the more familiar version.
with $x$ pigeons and $x^2$ holes (i.e. replace in (9) the bounds $x|y|$ and $x(|y| + 1)$ by $x$ and $x^2$ respectively). Now, if $S^1_2 + sWPHP(PV)$ proves $\exists y \varphi(y, x)$, then, following Thapen’s proof of [59, Theorem 4.2] (based on [58, Section 2]; cf. also [26, Proposition 1.14]), there are $\ell_0 \in \mathbb{N}$ and a unary $h \in PV$ such that $S^1_2$ proves

$$\exists y \varphi(y, x) \lor \forall v < 2^{8|x|^\ell_0} \exists u < 2^{4|x|^\ell_0} h(u) = v.$$  

By Buss’ Witnessing Theorem 2.1 it now suffices to show that for every (standard) positive rational $\epsilon < 1$ there is $\ell \in \mathbb{N}$ such that $S^1_2$ proves

$$\forall v < 2^{8|x|^\ell_0} \exists u < 2^{4|x|^\ell_0} h(u) = v \rightarrow (|N| \geq |x|^{\ell} \rightarrow \exists C \neg LB_{tt}(f, C, |N|^\epsilon, n, N)).$$

Argue in $S^1_2$ and set $m := 4|x|^\ell_0$. There is $\ell_1 \in \mathbb{N}$ such that $h$ on $2^m$, a surjection from $2^n$ onto $2^{2^m}$, is computed by a circuit of size $m^{\ell_1}$. Following Jeřábek’s $S^1_2$-proof of [26, Proposition 3.5], this implies that every (number) $f$ viewed as a truth table of length $|f|$ is computed by a size $O(m|m| + m^{\ell_1} \cdot ||f|m||)$ circuit with $||f||$ variables. Set $n := ||f||$ and $N := 2^n - 1$, so that $2^n = |N|$. The size of this circuit is $\leq |f|^\epsilon \leq |N|^\epsilon$ if $\ell \in \mathbb{N}$ is sufficiently large and if $|N| = 2^{|f||} \geq |x|^\ell$ and hence $|f| \geq |x|^\ell/2$. $\square$

Recall the formulas (36) from Section 4.2. The following is our main result concerning upper bounds on the $\text{lb}_w$-formulas.

**Theorem 4.10.** Let $Q \subseteq \mathbb{N}$ be $\Sigma^b_0$-defined, $k, n_0 \in \mathbb{N}$ and $0 < \epsilon < 1$. If $\text{APC}_1$ proves

$$n_0 \leq x \rightarrow \text{LB}[C, Q](C, x^k, x, N),$$

then there are $\ell \in \mathbb{N}$, $w(C, x, N, \tilde{f}, \tilde{x}, \tilde{N}) \in PV$, $\text{circ}(C, x, N, \tilde{f}, \tilde{x}, \tilde{N}) \in PV$ and a polynomial time algorithm which given $2^m$ and $n$ in unary such that

$$n \geq n_0 \text{ and } m \geq (k + 1)\ell \log n$$

computes an $\text{EF}$-proof of

$$\forall a < 2^m \ " \text{circ}(C, x, N, \cdot)(a) \neq \tilde{f}(a)" \ [n/x, 2^n - 1/N]$$

$$\rightarrow \text{lb}_{w(..., \tilde{f}, \tilde{x}, \tilde{N})}[C, Q, n^k] [m/\tilde{x}, 2^{2^m} - 1/\tilde{N}];$$

(40)

moreover, $\text{PV}_1$ proves that $\text{circ}(C, x, N, \tilde{f}, \tilde{x}, \tilde{N})$ is a circuit of size $\leq |\tilde{N}|^\epsilon$.

It follows from earlier conventions that the length bounds associated to $\tilde{f}, \tilde{C}, \tilde{x}, \tilde{N}$ are $2^m, 2^m, |m|, 2^m$, and those associated to $C, x, N$ are $n^{k+1}, |n|, n$. Aside some auxiliary variables, the formula (40) has variables corresponding to $C$ and $\tilde{f}$, both appearing before and after $\rightarrow$. Observe that (40) has size $n^{O(1)}$ for $m := [(k + 1)\ell \log n]$. 

37
Proof. By the lemma there are $\text{circ}, w \in \text{PV}$ and $\ell \in \mathbb{N}$ such that $\text{PV}_1$ proves

$$|\tilde{N}| \geq |N|^{(k+1)^\ell} \geq n_0^{(k+1)^\ell}$$

$$\land \, \text{LB}_{tt}(f, \text{circ}(C, x, N, \tilde{f}, \tilde{x}, \tilde{N}), |\tilde{N}|^\epsilon, \tilde{x}, \tilde{N})$$

$$\rightarrow \text{LB}^0[C, Q](C, x^k, x, N, w(C, x, N, \tilde{f}, \tilde{x}, \tilde{N})), \tag{41}$$

Here, we used $\max\{|C|, |x|, |N|\} \leq |N|^{k+1}$ if $x = |N|$; this holds because then $|C|$ is implicitly bounded in $\text{LB}^0[C, Q]$ by $x^{k+1}$. It is easy to ensure that $\text{circ}$ satisfies the “moreover” part of the theorem; if necessary modify the function changing every output which is not a size $\leq |\tilde{N}|^\epsilon$ circuit to some such circuit not computing $f$.

We apply the translation and a substitution to (41). By Cook’s Simulation Theorem 4.1, there is a polynomial time algorithm computing $\text{EF}$-proofs of the formulas

$$\left(\left[|\tilde{N}| \geq |N|^{(k+1)^\ell} \geq n_0^{(k+1)^\ell}\right]\right)$$

$$\land \left[\text{LB}_{tt}(f, \text{circ}(C, x, N, \tilde{f}, \tilde{x}, \tilde{N}), |\tilde{N}|^\epsilon, \tilde{x}, \tilde{N})\right]$$

$$\rightarrow \left[\text{LB}^0[C, Q](C, x^k, x, N, w(C, x, N, \tilde{f}, \tilde{x}, \tilde{N}))\right][m/\tilde{x}, 2^m - 1/\tilde{N}, n/x, 2^n - 1/\tilde{N}]. \tag{42}$$

This is (40) if we can eliminate the first conjunct (42). But since $m \geq (k + 1)\ell \log n$ and $|N| \geq n_0$, after the substitution (42) is a tautology whose variables are only the auxiliary variables used in the definition of the translation. These do not appear elsewhere in the formula, so substituting them by arbitrary values gives a true propositional formula without variables which is easy to prove. \qed

### 4.5 Succinct tautologies via anticheckers

A rather crude way to define succinct formulas expressing circuit lower bounds is to restrict the disjunction $\bigvee_{a<2^n}$ in (37) to a small subdisjunction:

**Definition 4.11.** Let $Q \subseteq \mathbb{N}$ be $\Sigma_0^b$-defined. An antichecker is a sequence $A = (A_n)_{n \in \mathbb{N}}$ of subsets $A_n \subseteq [0, 2^n)$. It is polynomially bounded if $|A_n| \leq n^{O(1)}$.

Given an antichecker $A$ define

$$\text{lb}_A[C, Q, n^k] := \bigvee_{a \in A_n} "C(a) \not= Q(a)" \tag{43}$$

The size of this formula is $(|A_n| + n)^{O(1)}$. We do not mention $C$ if it is the class of all circuits, thus writing $\text{lb}_A[Q, n^k]$.

The following is a classical result from [41]:

**Theorem 4.12 (Lipton, Young 1994).** Let $Q \subseteq \mathbb{N}$ be $\Sigma_0^b$-defined. For all $k \in \mathbb{N}$ there exists $\ell \in \mathbb{N}$ such that if $\text{tt}[Q, n^k]$ is tautological, then $\text{lb}_A[Q, n^k]$ is tautological for some antichecker $A = (A_n)_{n \in \mathbb{N}}$ with $|A_n| \leq n^\ell$ for all sufficiently large $n \in \mathbb{N}$. 38
The \( A \)-formulas as well as the \( w \)-formulas could be hard tautologies for EF or Frege, and the hope is that this might be easier to show than for the tt-formulas. Intuitively, the \( A \)-formulas are even harder than the tt-formulas because they are, for polynomially bounded anticheckers, exponentially shorter but have the same meaning. We give some evidence for this intuition showing that hardness of \( A \)-formulas for Frege follows from hardness of tt-formulas for constant depth Frege. Being hard for constant depth Frege means being hard for depth \( d \) Frege for all \( d \in \mathbb{N} \).

Here we use some common mode of speech: a set \( \Gamma \) of propositional formulas has short proofs in a given proof system (and it is hard otherwise), if there is a polynomial \( p \) such that every \( F \in \Gamma \) has a proof of size \( p(|F|) \) in the system (\(|F|\) is the length of the binary string encoding \( F \)).

To feed tt-formulas into constant depth Frege we reformulate them as DNFs:

**Lemma 4.13.** There is a polynomial time computable function that maps every propositional formula \( F \) to a DNF \( \text{DNF}(F) \) such that

(a) \( F \) is tautological if and only if so is \( \text{DNF}(F) \);

(b) the set of formulas of the form \( (F \rightarrow \text{DNF}(F)) \) has short Frege proofs.

The proof is standard using extension variables for subformulas of \( F \) and goes back to Tseitin [62, pp.115f]. We leave it to the reader.

**Proposition 4.14.** Let \( Q \subseteq \mathbb{N} \) be \( \Sigma_0 \)-defined, \( k \in \mathbb{N} \) and \( I \subseteq \mathbb{N} \) infinite. If the formulas

\[
\text{tt}[Q, n^k]^{\text{DNF}} := \bigvee_{a < 2^n} \text{DNF}(“C(a) \neq Q(a)”)
\]

for \( n \in I \) are hard for constant depth Frege, then for all polynomially bounded anticheckers \( A = (A_n)_{n \in \mathbb{N}} \) the formulas \( \text{lb}_{A}[Q, n^k], n \in I, \) are hard for (unbounded depth) Frege.

**Proof.** Suppose there is a polynomially bounded antichecker \( A \) and an infinite \( I \subseteq \mathbb{N} \) such that the formulas \( \text{lb}_{A}[Q, n^k], n \in I, \) have short Frege proofs. By Lemma 4.13 (b) there are short Frege proofs of \( \bigvee_{a \in A_n} \text{DNF}(“C(a) \neq Q(a)”), n \in I. \) We can assume the conjunctions and disjunctions are written in a balanced form so that the formula has logical depth \( O(\log n) \) (i.e. the formula tree has this depth). Then the main result of Filmus et al. [24, Theorem 3.1] (see [43] for a model-theoretic proof) applies and implies that for sufficiently large \( d \in \mathbb{N} \) our formula has depth \( d \) Frege proofs of size \( 2^{O(n)} \). Weakening gives size \( 2^{O(n)} \) Frege proofs of \( \text{tt}[Q, n^k]^{\text{DNF}}. \) Since \( \text{tt}[Q, n^k]^{\text{DNF}} \) has size \( \geq 2^n \) these proofs are short. \( \square \)

Note that \( \text{lb}_{A}[C, Q, n^k] \) states that the partial truth table \( \{(a, Q(a)) \mid a \in A_n\} \) cannot be computed by a size \( \leq n^k \) circuit in \( C. \) We aim to prove a non-uniform version of this formula where instead of a fixed problem \( Q \) we have a partial truth table \( f \) as input. Identify a partial function \( f \) on \( \{0,1\}^n \) with its graph

\[
f = \{(a_i, b_i) \in \{0,1\}^n \times \{0,1\} \mid i < \ell\},
\]

(44)
where \( \ell \in \mathbb{N} \) is the size of \( f \). Then formula \( \text{ptt}[C, f, s(n), n, \ell] \) has the form

\[
\forall i < \ell \ "C(a_i) \neq b_i" 
\]

and expresses that there are no size \( s(n) \) \( C \)-circuits computing \( f \). Before giving the definition, we informally point out a motivation from learning: given \( \ell \) data about a function \( f \) as above we wish to predict the value \( f(a_\ell) \) on a new input \( a_\ell \in \{0, 1\}^n \). For this to make sense we have to assume that this value is determined by the \( \ell \) given data, so \( f(a_\ell) \) is computed by any minimal size circuit \( C \) computing \( f \) on \( a_0, \ldots, a_{\ell-1} \). Say, the minimal circuit \( C \) has size \( s(n) \). Then the task to predict the bit \( f(a_\ell) \) can be formulated as the task to prove the lower bound \( (45) \) for circuits of size \( s(n) \) and with extra disjunct \( "C(a_i) \neq b" \) for the bit \( b := 1 - f(a_\ell) \). It has recently been demonstrated that natural proofs of circuit lower bounds indeed imply the existence of learning algorithms [13].

To define the formula \( (45) \) we give an ad hoc formalization of lower bounds for partial functions in bounded arithmetic and apply the propositional translation. We remind the reader that our choice is immaterial to a large extent, namely \( \text{EF} \)-provable equivalence.

View \( f \) as in \( (44) \) as a number \( f < 2^{\ell(n+1)} \) in turn viewed as a binary string consisting of \( \ell \) blocks of length \( n + 1 \), the \( i \)-th one being given by \( [f]_{i}^{n,\ell} < 2^{n+1} \) and meant to code the \( i \)-th pair \( (x_i, b_i) \) in \( (44) \); formally, \( x_i = \left[ f_{i}^{n,\ell} / 2 \right] < 2^n \) and \( b_i = \text{bit}(0, [f]_{i}^{n,\ell}) < 2 \). We formalize this using for \( n, \ell \) variables \( x, z \) with associated dummy variables \( N, L \). Further, we use \([u]_{i}^{x,z}\) as a function symbol in \( \text{PV} \). Then the following \( \text{PV}_1 \)-formula expresses a size \( s \) \( C \)-circuit lower bound for the partial truth table \( u < 2^{z-(x+1)} \):

\[
\text{LB}_{\text{ptt}}[C](u, C, s, x, N, z, L) := \\
\exists i < |L| \left( u < L\#(2N) \land x = |N| \land z = |L| \land C \text{ is a } C \text{-circuit of size } \leq s \rightarrow C([u]_{i}^{x,z} / 2) \neq \text{bit}(0, [u]_{i}^{x,z}) \right).
\]

Note this formula holds trivially if \( u \) does not code a partial function (i.e. codes pairs \( (a, 0) \) and \( (a, 1) \) for some \( a \in \{0, 1\}^n \)).

**Definition 4.15.** Let \( s(x) \in \text{PV}_1 \) and recall a circuit of size \( \leq s(n) \) is coded by a number of length \( \leq c \cdot s(n) \cdot \log s(n) \) for a suitable constant \( c \in \mathbb{N} \). Associate with \( u, C, x, N, z, L \) length bounds \( \ell \cdot (n+1), c \cdot s(n) \cdot \log s(n), |n|, n, |\ell|, \ell \) and define

\[
\text{ptt}[C, f, s(n), n, \ell] := \\
\left[ \text{LB}_{\text{ptt}}[C](u, C, s(x), x, N, z, L) \right] [f/u, n/x, 2^n - 1/N, \ell/z, 2^\ell - 1/L].
\]

Observe that the quantifier \( \exists i < |L| \) translates to a disjunction \( \bigvee_{i<\ell} \), so \( \text{ptt}[C, f, 2^{|n|^2}, n, \ell] \) is of the form \( (45) \) as desired. Further note that the size of this formula is \( (s(n) \cdot \ell \cdot n)^{O(1)} \).
4.6 Propositional naturalization of Smolensky’s proof

In this section we formalize a variant of Razborov and Rudich’s naturalization of Smolensky’s \( \text{AC}^0[p] \)-lower bound proof, “the most difficult example of naturalization we have encountered” [56, Section 3.2.1]. This will allow us to construct \( \text{WF} \) proofs of formulas \( \text{ptt}[\text{AC}^0[p], f, n \# n, n, \ell] \) for all partial functions \( f \) satisfying a technically defined property which is in some sense large, constructive and useful (cf. Theorem 3.26).

To define our succinct natural property we need some notation. Let \( f = f(x_1, \ldots, x_n) \) be a partial Boolean function on \( n \) Boolean variables \( x_1, \ldots, x_n \), and let \( \rho \) be a restriction on these variables leaving \( n' \) variables unassigned. Then \( f|\rho := f(\rho(x_1), \ldots, \rho(x_n)) \) is a partial Boolean function on \( n' \) variables with domain \( \subseteq \{0,1\}^{n'} \). By abuse of notation we shall denote these \( n' \) variables by \( x_1, \ldots, x_{n'} \). We shall be interested in partial functions which have sufficiently large domain in the sense that \( f|\rho \) is total for some \( \rho \) leaving polylogarithmically many variables unassigned.

Let \( p, q \in \mathbb{N} \) be distinct primes, \( \omega \neq 1 \) a \( q \)-th root of unity in \( \mathbb{F}_{pq^{-1}} \), and \( \mathcal{P} \subseteq \mathbb{F}_{pq^{-1}}[x] \) a set of polynomials in the variables \( x = (x_1, \ldots, x_{n'}) \). We define a \( 2^{n'} \times |\mathcal{P}| \) matrix \( M_{p,q}(\mathcal{P}) \) over \( \mathbb{F}_{pq^{-1}} \): its rows are indexed by tuples \( a \in \{\omega, 1\}^{n'} \), its columns by \( P(x) \in \mathcal{P} \), and the \((a, P(x))\)-th entry is the value \( P(a) \in \mathbb{F}_{pq^{-1}} \). Further, for a polynomial \( P_0(x) \) we write

\[
M_{p,q}(P_0) := M_{p,1}(P_0 \cdot \mathcal{L}_n \cup \mathcal{L}_n')
\]

where \( \mathcal{L}_n' \) denotes the low degree monomials (we agree that \( \Pi_{i \in \emptyset} x_i = 1 \)):

\[
\mathcal{L}_n := \left\{ \Pi_{i \in T} x_i \mid T \subseteq [n'], |T| \leq n'/2 \right\}. \tag{46}
\]

For \( g : \{0,1\}^{n'} \rightarrow \{0,1\} \) let \( P[g] \in \mathbb{F}_{pq^{-1}}[x] \) denote the multilinear polynomial which is “the same” as \( g(x) \) but with 0,1 replaced by 1,\( \omega \); in particular, \( P[g] \) maps \( \{\omega, 1\}^{n'} \) into \( \{\omega, 1\} \). The proof of Theorem 3.12 shows how to explicitly write down a multilinear polynomial \( p(x) \) coinciding with the function \( g' : \{\omega, 1\}^{n'} \rightarrow \{0,1\} \) defined as \( g \) under the inputwise substitution \( y = \frac{x-1}{\omega-1} \); then set

\[
P[g](x) := (\omega - 1)p(x) + 1.
\]

In particular, there is a polynomial time algorithm which given the truth table of \( g \) computes \( P[g] \) explicitly as a list of coefficients.

**Theorem 4.16.** Let \( p, q \in \mathbb{N} \) be distinct primes, \( d \in \mathbb{N} \) and \( 0 < \epsilon < 1 \) a rational. There are \( c, n_0 \in \mathbb{N} \) and \( \text{circ}(r, u, C, x, N, z, L, f, \tilde{x}, N) \in \text{PV} \) and a polynomial time algorithm which given \( 2^k \) in unary and \( f, \rho \) such that for some \( \ell, n \in \mathbb{N} \) and \( m := \lceil \log^d n \rceil \)

(i) \( f \) is a size \( \ell \) partial Boolean function on \( n \) variables and \( \rho \) a restriction leaving \( m + q \) variables unassigned,
(ii) \( f \mid \rho : \{0, 1\}^{m+q} \rightarrow \{0, 1\} \) is total and \( M_{p,q}(P[f \mid \rho]) \) has rank at least \( 3/4 \cdot 2^m \),

(iii) \( n \geq n_0 \) and \( k \geq c \cdot \log(\ell n) \),

computes an EF-proof of

\[
\bigvee_{a < 2^k} "\text{circ}(r, u, C, x, N, z, L, \cdot)(a) \neq \tilde{f}(a)" \quad [\rho/r, f/u, n/x, 2^m - 1/N, \ell/z, 2^\ell - 1/L] \\
\rightarrow \text{ptt}[\text{AC}_d^0[p], f, 2|n|^2, n, \ell];
\]

moreover, \( \text{PV}_1 \) proves that \( \text{circ}(r, u, C, x, N, z, L, \tilde{f}, \tilde{x}, \tilde{N}) \) is a circuit of size \( \leq |\tilde{N}|^\epsilon \).

Proof. Jeřábek [27, Theorem 4.3.18] showed that there exists a PV-function which \( \text{PV}_1 \)-provably computes from a given matrix \( M \) over \( \mathbb{F}_{p^{\ell-1}} \) a sequence of elementary matrices bringing \( M \) in reduced row echelon form. In particular, there exists a PV-symbol which \( \text{PV}_1 \)-provably computes from \( M \) a subset (of indices) of rows which form a basis for the row space of \( M \). Given \( f, \rho \) with (i) and (ii) one can compute in polynomial time (the list of coefficients of) the multilinear polynomial \( P[f \mid \rho] \) and the matrix \( M_{p,q}(P[f \mid \rho]) \), explicitly as a tuple in \( \mathbb{F}_p^{2m+q} \times \mathbb{F}_p^{2m+q} \) (note (ii) implies that \( f \) has size \( \ell \geq 2^m \)). Hence, (i) and (ii) are expressible by \( \Sigma_0^b \)-formulas with variables \( u, r, x, z \) for \( f, \rho, n, \ell \).

We claim that \( S_1^1 + \text{swPHP}(\text{PV}) \) proves the \( \Sigma_0^b \)-formula

\[
\varphi(r, u, C, x, N, z, L) := \\
x \geq n_0 \rightarrow (u, r, x, z \text{ satisfy (i) and (ii)} \rightarrow \text{LB}_{\text{ptt}}[\text{AC}_d^0[p]](u, C, x\#x, x, N, z, L)).
\]

We argue in \( S_1^1 \) that the \( \neg \varphi \) contradicts \( \text{swPHP}(\text{PV}) \). For readability we write again \( f, \rho, n, \ell \) instead \( u, r, x, z \). Assume the antecedens of \( \varphi \) and that \( C \) is a size \( \leq n\#n \text{ AC}_d^0[p] \)-circuit computing \( f \mid \rho : 2^m \rightarrow 2 \) where \( m := \lceil \log^{3d} n \rceil \). Note this implies \( 2^{m+q} \in \text{Log} \).

Now follow the proof of Theorem 3.9 and construct an arithmetical circuit \( P \) by replacing gates of \( C \) by low-degree polynomials: setting the parameters \( \ell, \epsilon \) appropriately, we get \( P(x) = (f \mid \rho)(x) \) with probability \( 1 - 1/2^{4+q} \) over \( x < 2^m \) and that \( P(x) \) has syntactic degree \( O(|n|^{2d}) \). As \( 2^{m+q} \in \text{Log} \), all probabilities can be counted precisely and stated by a \( \Sigma_0^b \)-formula. To define \( P(x) \), thus \( \text{BB}(\Sigma_0^b) \) is sufficient and this scheme is available in \( S_1^2 \).

Applying the inputwise substitution \( y = \frac{x}{\omega - 1} \) to \( P \) and replacing its output \( z \) by \( (\omega - 1)z + 1 \), gives an arithmetical circuit \( P' \) of the same syntactic degree such that \( P'(x) = P[f, \rho](x) \) for many \( x \), namely, for all \( x \) from some set \( X \subseteq \{\omega, 1\}^{m+q} \) of cardinality \( \text{Card}(X) \geq (1 - 1/2^{4+q}) \cdot 2^{m+q} \).

As mentioned above, we can compute in \( \text{PV} \) a subset \( X' \subseteq \{\omega, 1\}^{m+q} \) of indices of rows forming a basis of the row space of \( M_{p,q}(P[f \mid \rho]) \). By (ii), \( \text{Card}(X') \geq 3/4 \cdot 2^m \), so \( X'' := X \cap X' \) has cardinality \( \text{Card}(X'') > 2/3 \cdot 2^m \). The rows with index in \( X'' \) are the same in the matrices \( M_{p,q}(P[f \mid \rho]) \) and \( M_{p,q}(P') \). The columns of \( M_{p,q}(P') \) are indexed by polynomials of degree \( \lfloor (m+q)/2 \rfloor + O(|n|^{2d}) < \lfloor \frac{m}{2} \rfloor + m^{1/3} \) assuming \( n_0 \) and hence \( n, m \).
are large enough. Thus, every function $h : X'' \to \mathbb{F}_{p^e-1}$ can be written as a polynomial of at most this degree. This contradicts the $\text{sWPHP}(\text{PV})$ (see the proof of Theorem 3.12).

We now proceed similarly as in the proof of Theorem 4.10. Abbreviating the variables $r, u, C, x, N, z, L$ of $\varphi$ by $\bar{x}$ for readability, Lemma 4.9 gives a constant $c' \in \mathbb{N}$ and a function $\text{circ}(\bar{x}, \tilde{f}, \tilde{x}, \tilde{N}) \in \text{PV}$ such that $\text{PV}_1$ proves

$$|\tilde{N}| \geq |\bar{x}|^{c'} \wedge \text{LB}_{tt}(\tilde{f}, \text{circ}(\bar{x}, \tilde{f}, \tilde{x}, \tilde{N}), |\tilde{N}|^c, \tilde{x}, \tilde{N}) \to \varphi(\bar{x}).$$

(49)

As in Theorem 4.10 we find such $\text{circ}$ satisfying the “moreover” part of the theorem.

We now describe the polynomial time algorithm. On input $(2^k, f, \rho)$ satisfying (i)-(iii) for certain $n, \ell$, it first runs the algorithm from Theorem 4.1 to get an $\text{EF}$-proof of the translation of (49) for the following association of length bounds to the variables. With the variables $u, C, x, N, z, L$ associate $\ell \cdot (n + 1), 2^{|n|^3}, |n|, |n|, |\ell|, \ell$, and with $r$ some length bound $n^{O(1)}$ suitable to hold an encoding of the restriction $\rho$; note length $2^{|n|^3}$ is enough to code a circuit of size $\leq n \# n$. With the variables $\tilde{f}, \tilde{x}, \tilde{N}$ associate $2^k, |k|, 2^k$.

The time needed to construct this $\text{EF}$-proof is polynomial in these length bounds, so polynomial in the length of the input (note $|f| \geq \ell \geq 2^{\log^9 n}$).

Next the algorithm applies the substitution

$$[k/\tilde{x}, 2^{2k} - 1/\tilde{N}, \rho/r, f/u, n/x, 2^n - 1/N, \ell/z, 2^\ell - 1/L]$$

to the proof. If $c \in \mathbb{N}$ in (iii) is large enough, then $[|\tilde{N}| \geq |\bar{x}|^{c'}]$ as well as the antecedents of $[\varphi]$ become tautologies in auxiliary variables only, so can be eliminated (see the proof of Theorem 4.10). This yields an $\text{EF}$-proof of the formula

$$[\text{LB}_{tt}(\tilde{f}, \text{circ}(\bar{x}, \tilde{f}, \tilde{x}, \tilde{N}), |\tilde{N}|^c, \tilde{x}, \tilde{N})] \to [\text{LB}_{tt}[\text{AC}_d^0[p]](u, C, |N| \# |N|, x, N, z)]$$

with the above substitution. This is (47).

As a corollary to the previous proof we get:

**Corollary 4.17.** Let $p, q \in \mathbb{N}$ be distinct primes and $d \in \mathbb{N}$. There are $n_0 \in \mathbb{N}$ and a polynomial time algorithm which given $f, \rho$ such that for some $\ell, n \in \mathbb{N}$ and $m := \lceil \log^9 n \rceil$

(i) $f$ is a size $\ell$ partial Boolean function on $n$ variables and $\rho$ a restriction leaving $m+q$ variables unset,

(ii) $f \upharpoonright \rho : \{0, 1\}^{m+q} \to \{0, 1\}$ is total and $M(P[f \upharpoonright \rho])$ has rank at least $3/4 \cdot 2^m$,

(iii) $n \geq n_0$,

computes a $\text{WF}$-proof of $\text{ptt}[\text{AC}_d^0[p], f, 2^{\lceil n \rceil^2}, n, \ell]$.  

43
Proof. As seen in the previous proof $S_2^1 + sWPHP(PV)$ proves the $\Sigma^0_0$-formula $\phi$. By Theorem 4.2 we can produce a WF-proof of $\parallel \phi \parallel$ with length bounds as in the previous proof. As there, applying an appropriate substitution allows to eliminate the antecedents, leaving a proof of $\text{ptt}[\text{AC}^0_d[p], f, 2^{m^2}, n, \ell]$.

\[ 2 \] The argument $\rho$ to the algorithms in Theorem 4.16 and Corollary 4.17 can be omitted by slightly increasing the running time: given $f$ one can compute in time $n^{O(m)}$ some $\rho$ such that (i) and (ii) hold, provided there exists one. In particular, fixing $k := [c \cdot \log(\ell n)]$ in Theorem 4.16, we get quasipolynomial time algorithms with single input $f$.

**Corollary 4.19.** Let $p, q \in \mathbb{N}$ be distinct primes and $d \in \mathbb{N}$. There are $n_0 \in \mathbb{N}$ and a quasipolynomial time algorithm that given $n \geq n_0$ in unary computes a WF-proof of

$$\text{ptt}[\text{AC}^0_d[p], f, 2^{m^2}, n, 2^{m+q}],$$

where $f$ is the MOD$_q$ function restricted to $\{0, 1\}^{m+q} \times \{0\}^{n-m-q}$ with $m := \lceil \log^{9d} n \rceil$.

**Proof.** Let $\rho$ be the restriction on the variables $x_1, \ldots, x_n$ that leaves $x_1, \ldots, x_{m+q}$ unassigned and maps $x_{m+q+1}, \ldots, x_n$ to 0. Then $f = f | \rho$ equals $\text{MOD}_q$ on $\{0, 1\}^{m+q}$.

For $i < q$ let $b_i \in \{\omega, 1\}^q$ be a tuple with $q - i$ many $\omega$’s and $i$ many 1’s. Then

$$\prod_{i \in [m]} x_i = \sum_{i < q} \omega^i \cdot \frac{P[f, \rho](x_1, \ldots, x_m, \bar{b}_i) - 1}{(\omega - 1)}. \quad (50)$$

Observe that $M_{p,q}(P[f, \rho])$ and $M_{p,q}(P[f, \rho] - 1)$ have the same rank, and we show the latter one is large. Then our claim follows from Corollary 4.17.

Consider the columns of $M_{p,q}(P[f, \rho] - 1)$ indexed by $(P[f, \rho] - 1) \cdot Q$ where $Q \in \mathcal{L}_m \subseteq \mathcal{L}_{m+q}$ (see (46)). By (50), there is a linear combination of rows of $M_{p,q}(P[f, \rho] - 1)$ such that every such column is transformed to a column containing (as a subtuple the course of values of) the function $(\prod_{i \in [m]} x_i) \cdot Q$. As seen in the proof of Theorem 3.12, every function $h(x_1, \ldots, x_m)$ from $\{\omega, 1\}^m$ to $\{\omega, 1\}$ is a linear combination of $(\prod_{i \in [m]} x_i) \cdot \mathcal{L}_m \cup \mathcal{L}_m$. This means that the image of $M_{p,q}(\prod_{i \in [m]} x_i)$ contains all these functions. So $M_{p,q}(\prod_{i \in [m]} x_i)$ and hence also $M_{p,q}(P[f, \rho] - 1)$ has rank $\geq 2^m$.

Recalling the motivation from learning, we finally observe for $q = 2$ that there are many partial functions satisfying (ii) in Theorem 4.16.

**Proposition 4.20.** Let $p > 2$ be prime and $n' \in \mathbb{N}$. Then the $2^n' \times 2^n'$ matrix $M_{p,2}(P[g])$ over $\mathbb{F}_p$ has rank at least $3/4 \cdot 2^n'$ for at least half of all functions $g : \{0, 1\}^{n'} \rightarrow \{0, 1\}$.
Proof. Let us call a polynomial over \( \mathbb{F}_p \) with variables \( x = (x_1, \ldots, x_{n'}) \) representing if it maps \( \{-1, 1\}^{n'} \) into \( \{-1, 1\} \). Obviously, representing polynomials are closed under multiplication. We claim that for every representing \( P = P(x) \) at least one of the matrices \( M_{p,2}(P) \) or \( M_{p,2}(P \cdot \prod_{i \in [n']} x_i) \) has rank \( \geq 3/4 \cdot 2^{n'} \).

For a set \( \mathcal{P} \) of representing polynomials, let \( V(\mathcal{P}) \) denote the vector space spanned by the columns of \( M_{p,2}(\mathcal{P}) \). Observe that for a representing \( P(x) \in \mathbb{F}_p[x] \) we have

\[
\dim(V(\mathcal{P})) = \dim(V(P \cdot \mathcal{P})).
\]

Indeed, \( M_{p,2}(P \cdot \mathcal{P}) \) is obtained from \( M_{p,2}(\mathcal{P}) \) by multiplying every row with a non-zero scalar, namely \( P(a) \in \{-1, 1\} \) for the row with index \( a \in \{-1, 1\}^{n'} \), and this preserves the rank.

For the set of monomials \( \mathcal{M}_{n'} := \{ \prod_{i \in T} x_i \mid T \subseteq [n'] \} \) we have \( \dim(V(\mathcal{M}_{n'})) = 2^{n'} \) because every function from \( \{-1, 1\}^{n'} \) to \( \{-1, 1\} \) is computed by a multilinear representing polynomial. Further, we have \( \mathcal{M}_{n'} = (\prod_{i \in [n']} x_i) \cdot \mathcal{L}_{n'} \cup \mathcal{L}_{n'} \) and \( \dim(V(\mathcal{L}_{n'})) = 1/2 \cdot 2^{n'} \).

We aim to show that the dimension of \( V((P \cdot \mathcal{L}_{n'} \cup \mathcal{L}_{n'})) \) or \( V((P \cdot \prod_{i \in [n']} x_i) \cdot \mathcal{L}_{n'} \cup \mathcal{L}_{n'}) \) is \( \geq 3/4 \cdot 2^{n'} \). Using (51) and noting \( P^2 = 1 \) we get

\[
\begin{align*}
\dim V((P \cdot \prod_{i \in [n']} x_i) \cdot \mathcal{L}_{n'} \cup \mathcal{L}_{n'}) &= \dim V(\mathcal{L}_{n'}) - \dim V(P \cdot \mathcal{L}_{n'}) \\
&= \dim V(\prod_{i \in [n']} x_i) \cdot \mathcal{L}_{n'} \cup P \cdot \mathcal{L}_{n'}) - \dim V(P \cdot \mathcal{L}_{n'}) \\
&= \dim \left( \frac{V((P \cdot \prod_{i \in [n']} x_i) \cdot \mathcal{L}_{n'} \cup P \cdot \mathcal{L}_{n'})}{V(P \cdot \mathcal{L}_{n'})} \right) \\
&\geq \dim \left( \frac{V((\prod_{i \in [n']} x_i) \cdot \mathcal{L}_{n'} \cup P \cdot \mathcal{L}_{n'} \cup \mathcal{L}_{n'})}{V(P \cdot \mathcal{L}_{n'} \cup \mathcal{L}_{n'})} \right) \\
&= \dim V(\mathcal{M}) - \dim V(P \cdot \mathcal{L}_{n'} \cup \mathcal{L}_{n'}),
\end{align*}
\]

and thus

\[
\dim V((P \cdot \prod_{i \in [n']} x_i) \cdot \mathcal{L}_{n'} \cup \mathcal{L}_{n'}) + \dim V(P \cdot \mathcal{L}_{n'} \cup \mathcal{L}_{n'}) \geq 3/2 \cdot 2^{n'}.
\]

This implies our claim. \( \square \)

5 Questions

In the Introduction we said that a large part of contemporary complexity theory can be formalized in \( \text{PV}_1 \) or slight extensions of it. Table 1 lists some such results.

As announced in the Introduction we believe the given proofs of Theorems 1.1, 1.2 and 1.3 show that the \( \text{sWPHP}(\text{PV}) \) allows for a natural formalization of these circuit lower bounds. Remarks 3.8, 3.14 and 3.19 detail the role of the \( \text{sWPHP}(\text{PV}) \).

It is natural to ask whether the \( \text{sWPHP} \) can be avoided, that is, whether Theorems 1.1, 1.2 and 1.3 hold for \( \text{PV}_1 \) instead of \( \text{APC}_1 \). A positive answer for Theorem 1.2 could be

45
Theory | Theorem | Reference
---|---|---
P\text{V}_1 | Cook-Levin Theorem | folklore
PCP Theorem | [47]
Hardness amplification | [27]
AC\textsuperscript{0} | lower bounds | Section 3.2
AC\textsuperscript{0}[p] lower bounds (with \(2^{\log^{O(1)} n} \in \text{Log}\)) | Section 3.3
Monotone circuit lower bounds | Section 3.4
H\text{ARD}\textsuperscript{A} | Nisan-Wigderson’s derandomization | [26]
Impagliazzo-Wigderson’s derandomization | [27]
Goldreich-Levin theorem | [22]

Table 1: A list of formalizations.

interesting as this seems to require some new insights and a new proof. For Theorem 1.3
one might suspect a positive answer with a similar proof, vaguely because the circuits
witnessing the approximate counting are particularly simple and transparent. We have,
however, not been able to give such a proof.

On the other hand, proving independence from P\text{V}_1 is presumably very difficult. An
already challenging open problem is to show that the theory V\textsuperscript{0} corresponding to AC\textsuperscript{0}-
reasoning [21] does not prove LB(AC\textsuperscript{0}_d, \text{PARITY}) for \(s = n^k\), or, more precisely, a suitable
second-order formulation of this formula (see e.g. [46]).

A weaker task than finding P\text{V}_1-proofs is to derandomize the witnessing functions
derived from particular APC\textsuperscript{1}-proofs of circuit lower bounds. For instance and more precisely: is there a deterministic polynomial time Turing machine satisfying Corollary 3.21?

Concerning Theorem 1.2 we also leave open the question whether polynomial lower
bounds can be proved assuming only \(n \in \text{Log}\), that is: does APC\textsuperscript{1} prove LB(AC\textsuperscript{0}_d[p], \text{MOD}_q)
for \(s = n^k\) and large enough \(n \in \text{Log}\)?

On the propositional side the obvious question is whether our conditional upper bounds
can be made unconditional. For instance and more precisely: are there short EF-proofs of
lb\textsubscript{w}(AC\textsuperscript{0}_d, \text{PARITY}, n^k) for some w? It would already be interesting to find quasipolynomial
size WF-proofs. An interesting route to achieve this would be to witness LB(AC\textsuperscript{0}_d, \text{PARITY})
for \(s = n^k\) by a deterministic \(w \in \text{PV}\) provably in APC\textsuperscript{1}. This in turn could be achievable
by derandomizing the Switching Lemma formally in APC\textsuperscript{1} (cf. [61]). A positive answer
would be interesting not just for the lb\textsubscript{w}-formulation but any succinct formulation of AC\textsuperscript{0}_d-
lower bounds, for example, the ptt-formulation. Corollary 4.19 achieves WF-proofs of
AC\textsuperscript{0}_d[p] lower bounds for MOD\textsubscript{q} by formalizing the naturalization of this lower bound.

It is possible to approach similarly the naturalization of the AC\textsuperscript{0} lower bounds based
on the Switching lemma (see [56, Section 3.1]). Following the proof of Theorem 1.1, one can show how to generate a set of polynomially many restrictions such that every $\text{AC}^0$-circuit is collapsed by some of them. The set is generated by a probabilistic algorithm or, alternatively, using a Nisan-Wigderson generator based on a hard function. A candidate succinct natural property of partial functions $f$ would thus require for $f$ to be non-constant after any of the generated restrictions. However, it is not clear to us if this property is large in some sense. Moreover, WF-proofs of $\text{ptt}[\text{AC}^0, f, n^k, n, \ell]$ (say, for $f$ a partial PARITY) do not seem to follow since the property depends on the hard function of the Nisan-Wigderson generator.
