

On Constant-Depth Canonical Boolean Circuits for Computing Multilinear Functions

Oded Goldreich* Avishay Tal†

December 31, 2017

Abstract

We consider new complexity measures for the model of multilinear circuits with general multilinear gates introduced by Goldreich and Wigderson (*ECCC*, 2013). These complexity measures are related to the size of *canonical constant-depth Boolean circuits*, which extend the definition of canonical depth-three Boolean circuits. We obtain matching lower and upper bound on the size of canonical constant-depth Boolean circuits for almost all multilinear functions, and non-trivial lower bounds on the size of such circuits for some explicit multilinear functions.

1 Introduction

Goldreich and Wigderson [2] put forward a model of *depth-three canonical circuits*, with the underlying long-term goal of leading to better lower bounds for general depth-three Boolean circuits computing explicit *multi-linear* functions. Canonical circuits are restricted type of Boolean depth-three circuits, and their study is supposed to be a warm-up and/or a sanity check for the establishing of lower bound on the size of general depth-three Boolean circuits that compute explicit multi-linear functions.

The canonical circuits defined in [2] are *depth-three* Boolean circuits that are obtained by a two-stage process: First, one constructs arithmetic circuits that use arbitrary multilinear gates of parameterized arity, and next one converts these multilinear circuits to Boolean circuits. As shown in [2], the size of the resulting depth-three Boolean circuits is exponential in the maximum between the arity and the number of gates in the arithmetic circuit.

Hence, a natural complexity measure of such arithmetic circuits arises, and the immediate challenge posed by [2] is to present explicit t -linear functions on $t \cdot n$ variables that require complexity significantly greater than $(tn)^{1/2}$. Note that a lower bound of $m = \omega(\sqrt{tn})$ on the complexity of such a function f yields a lower bound of $\exp(m)$ on the size of depth-three canonical circuits computing f , whereas the best bound known on the size of a general depth-three Boolean circuit computing an explicit function over $\{0, 1\}^n$ is $\exp(\sqrt{n})$. Hence, in the context of the complexity measures of [2], a lower bound of $\omega(\sqrt{tn})$ is considered nontrivial.

In this context, a first nontrivial lower bound on an explicit function was obtained by Goldreich and Tal [3]. They exhibit explicit three-linear and four-linear functions having complexities $\Omega(n^{0.6})$ and $\Omega(n^{2/3})$, respectfully. Although there is still much to be understood about the foregoing model, which corresponds to depth-three canonical (Boolean) circuits, we dare take another speculative step and put forward a notion of constant-depth canonical (Boolean) circuits along with a corresponding model of arithmetic circuits. In particular:

- We define more permissive complexity measures than those defined in [2] and show a partial correspondence between them and a notion of constant-depth canonical circuit.
- Extending the results of [2], we obtain matching lower and upper bound on the complexity of almost all multi-linear functions. Specifically, for most t -linear functions, the size of canonical circuits of depth d is $\exp(\Theta(tn)^{t/(t+d-2)})$.¹
- Extending the results of [2] and using the results of [3], we obtain a lower bound on the size of depth-four canonical circuits that compute an explicit trilinear function. The resulting lower bound of $\exp(\tilde{\Omega}(n^{3/8}))$ should be compared to $\exp(\Omega(n^{1/3}))$, which is the best bound known on the size of a general depth-four Boolean circuit computing an explicit function over $\{0, 1\}^n$.

Our conceptual exposition (i.e., Sections 2 and 3) builds quite heavily on [2]. Familiarity with [2] may be useful also in the other sections. In contrast, the results of [3] are used as a black-box, and so familiarity with that paper is not needed here.

Organization. In Section 2 we recall the model of multi-linear circuits with general multi-linear gates, and present two complexity measures that refer to these circuits. These measures refine

¹Note that in the rest of the paper, the depth of the canonical circuits is denoted $d + 1$, whereas d corresponds to the depth of general multi-linear circuits.

and generalize the complexity measures introduced in [2], and offer a relation to canonical Boolean circuits of arbitrary constant-depth (rather than depth three), which is presented in Section 3.

In Section 4 we present matching lower and upper bounds on the foregoing complexity measures for almost all multilinear functions. These mark the lower bounds we should aim at for explicit functions. While we do not obtain these bounds, we do obtain non-trivial lower bounds in Sections 5–7. Specifically, in Section 5 we present bounds for an explicit trilinear function, and in Section 6 we present larger bounds for an explicit 4-linear function. In Section 7 we show that non-trivial lower bounds for one depth translate to non-trivial lower bounds for larger depths.

2 Definitions

The basic definitions of multilinear circuits are as in [2, 3]. The complexity measures, to be denoted \mathcal{C}_d and $\mathcal{C}^{(d-1)}$, will generalize the measures \mathcal{C}_2 and \mathcal{C} defined in [2] for the case of $d = 2$ (where $d + 1$ is the desired the depth of the canonical Boolean circuit). Recall that in [3], the corresponding complexity measures are called AN2-complexity and AN-complexity, where AN stands for Arity and Number of gates.

Multi-linear functions. For fixed $t, n \in \mathbb{N}$, we consider t -linear functions of the form $F : (\{0, 1\}^n)^t \rightarrow \{0, 1\}$, where F is linear in each of the t blocks of variables (which contain n variables each). Such a function F is associated with a t -dimensional array, called a **tensor**, $T \subseteq [n]^t$ such that

$$F(x^{(1)}, x^{(2)}, \dots, x^{(t)}) = \sum_{(i_1, i_2, \dots, i_t) \in T} x_{i_1}^{(1)} x_{i_2}^{(2)} \cdots x_{i_t}^{(t)} \quad (1)$$

where here $x^{(j)} = (x_1^{(j)}, \dots, x_n^{(j)}) \in \{0, 1\}^n$ for every $j \in [t]$.

Multi-linear circuits with general gates. These are multilinear circuits with arbitrary multilinear gates, of bounded arity (where this bound will serve as a complexity measure). The multilinear requirement mandates that if two gates have directed paths to them from the same block of inputs, then the results of these two gates are not multiplied together by any other gate.

Complexity measures. The main complexity measures are the *arity* of the general multilinear gates and the *number* of such gates, where we say that a multilinear circuit C has **arity** m if m equals the maximum arity of a general gate in C . For a multilinear function F , we denote by $\mathcal{C}_d(F)$ the minimum arity of a multilinear circuit of depth d that computes F , where the depth of a circuit is the distance between the input variable and the output gate (e.g., a circuit consisting of a top gate that computes the sum of multilinear gates that are fed by variables only has depth 2).

Note that the number of gates in a circuit of depth two and arity m is $m + 1$, since the last layer in the circuit contains only variables. Hence, $\mathcal{C}_2(\cdot)$ matches the notion of AN2-complexity as defined in [2, 3] (up to a slackness of one unit). In general, the number of gates in a circuit of depth d and arity m is at most $\sum_{i=0}^{d-1} m^i < (m + 1)^{d-1}$, because there are at most m^i gates at distance $i \leq d - 1$ from the output gate. (Note that gates in a depth d circuit are at distance at most $d - 1$ from the output gate, whereas only variables may be at distance d from the output gate.)

Letting $\mathcal{C}^{(e)}(F)$ denote the smallest m such that F can be computed by a circuit of arity at most m that has at most $(m + 1)^e$ gates, we have $\mathcal{C}^{(d-1)}(F) \leq \mathcal{C}_d(F)$. Note that AN-complexity as defined in [2, 3] equals $\mathcal{C}^{(1)}(\cdot)$ (again, up to a slackness of one unit).

3 Obtaining Boolean circuits

A direct implementation of the general multilinear gates in a multilinear circuits of depth d yields a Boolean circuit of depth $d + 1$ and size $\exp(O(\mathcal{C}_d(\cdot)))$. Specifically, we replace each general gate of arity m by a CNF (resp., a DNF) of size 2^m , where we use CNFs (resp., DNFs) in all even (resp., odd) levels. This allows to combine neighboring levels in the resulting depth $2d$ Boolean circuit, yielding a circuit of depth $d + 1$. (This generalizes the D-canonical circuits of [2, Cons. 2.6].)

Given a multilinear circuit C of arity m and at most $(m + 1)^e$ gates, we can obtain a Boolean circuit of depth $e + 2$ and size $\exp(O(m))$ in the special case that C can be *decomposed* into sub-circuits of depth e by omitting the edges that go out of at most m gates.² Specifically, we use a DNF of size $\tilde{O}(2^m)$ such that each of the 2^m conjunctions verifies a possible outcome of the computation of the m resulting sub-circuits, which in turn can be computed by $\exp(O(m))$ -size Boolean circuits of depth $e + 1$ (with a conjunction gate at the top). (This generalizes the ND-canonical circuits of [2, Cons. 2.8].)

More generally, we may call a circuit with N gates m -decomposable if omitting the outgoing edges of at most m of its gates yields sub-circuits that are each m -decomposable and have at most N/m gates. Then, the computation of any a m -decomposable multilinear circuit C that has arity m and at most $(m + 1)^e$ gates can be emulated by a Boolean circuit of depth $e + 2$ and size $\exp(O(m))$ as follows. The construction proceeds by induction on $e \geq 1$, where the case of $e = 1$ corresponds to [2, Cons. 2.8].

- For $e > 1$, suppose that C can be decomposed by omitting the outgoing edges of the gates G_1, \dots, G_m such that each G_i is the output gate of a sub-circuit that contains at most $(m + 1)^{e-1}$ gates. Then, by the induction hypothesis, each of the corresponding sub-circuits (as well as the sub-circuit rooted at the original output gate G_0) can be computed by a Boolean circuit of depth $e + 1$ and size $\exp(O(m))$.
- Consider a DNF that verifies the assertion *there exists $\alpha \in \{0, 1\}^m$ such that the outputs of (G_0, G_1, \dots, G_m) equal 1α* , where these $m + 1$ outputs correspond to computations that use the values of the original variables and use α_i as the value that replaces the outcome of G_i that is fed to any other gate. Then, combining this $\exp(m)$ -sized DNF with the aforementioned circuits of depth $e + 1$, we obtain the desired circuit.

Note that this leaves open the general case (where we are given a multilinear circuit of arity m that has at most $(m + 1)^e$ gates, but this circuit is not necessarily m -decomposable). Fortunately, the lower bounds (shown in the next sections) hold also for the general case. Still, we wonder what is the “right” notion of general AN-complexity for depth d . It is not inconceivable that a measure that requires decomposition is right, since it matches the natural application of the “Valiant method” [8].

4 Guiding Bounds

Analogously to [2], we have tight bounds on the complexities of almost all multilinear functions.

Theorem 4.1 (upper bound): *For every $d, t \in \mathbb{N}$, every t -linear function F satisfies $\mathcal{C}_d(F) = O(tn)^{t/(t+d-1)}$. Hence, $\mathcal{C}^{(d-1)}(F) = O(tn)^{t/(t+d-1)}$.*

²Actually, these out-going edges are omitted only from the sub-circuits from which they previously went out of. They are maintained as incoming edges in the sub-circuits that previously had them as such, but are fed by an auxiliary variable rather than by the output of the corresponding sub-circuit. (The DNF mentioned next refers to these auxiliary variables.)

This generalizes [2, Thm. 3.1], which was stated for $d = 2$.

Proof Sketch: Let $m = t \cdot n^{t/(t+d-1)} \approx (tn)^{t/(t+d-1)}$. Consider a partition of $[n]^t$ into cubes of side-length m/t , and gates that compute the corresponding multilinear functions. We have $(n/(m/t))^t = (tn/m)^t$ such gates, each of arity m . By our setting $(tn/m)^t \approx (m^{\frac{t+d-1}{t}-1})^t = m^{d-1}$, and so the sum of the m^{d-1} values of the aforementioned gates can be computed by a multilinear circuit of depth $d-1$ and arity m . Combining this circuit with the aforementioned gates, we obtain the desired circuit. ■

Theorem 4.2 (lower bound): *For every $d, t \in \mathbb{N}$, almost all t -linear functions F satisfy $\mathcal{C}^{(d-1)}(F) = \Omega((tn)^{t/(t+d-1)})$. Hence, $\mathcal{C}_d(F) = \Omega((tn)^{t/(t+d-1)})$.*

This generalizes [2, Thm. 4.1], which was stated for $d = 2$.

Proof Sketch: Letting $e = d - 1$, we upper-bound the number of general multilinear circuits of arity m and size $(m + 1)^e$. Ignoring the gates' functionalities, we note that the number of relevant DAGs is at most

$$\left(2^m \cdot \binom{tn + (m + 1)^e}{m}\right)^{(m+1)^e} < (((tn + 1)^e)^m)^{(m+1)^e} = \exp((m + 1)^{e+1} \log(tn + 1)^e),$$

where the inequality uses $tn + (m + 1)^e < (tn + 1)^e$. But (for $t \geq 2$ and $m \gg t \log n$) this is dominated by the number of possible gates' functionalities, which is

$$\left(2^{(m/t)^t}\right)^{(m+1)^e} = \exp(m^{t+e}/t^t),$$

since each gate corresponds to a tensor of volume at most $(m/t)^t$. The claim holds since $m^{t+e}/t^t \ll n^t$, provided that $m \ll (tn)^{t/(t+e)}$. ■

5 Lower Bounds on Explicit functions

Using the rigidity results of [3], one can obtain non-trivial lower on the \mathcal{C}_3 and $\mathcal{C}^{(2)}$ complexities of explicit trilinear functions, where by non-trivial we mean bounds significantly higher than $\Omega(n^{1/3})$ (which is easily obtained for parity). This relies on connections between the \mathcal{C}_3 and $\mathcal{C}^{(2)}$ complexities of bilinear functions and the rigidity of the corresponding matrices, which adapt ideas of [2]. We recall the relevant definition.

Definition 5.1 (matrix rigidity [7]): *A matrix A (over a field \mathcal{F}) has rigidity s for rank r if every matrix of rank at most r (over \mathcal{F}) differs from A on more than s entries.*

We shall consider bilinear functions in the variables $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$, and trilinear functions in the variables x, y and $z = (z_1, \dots, z_{2n-1})$.

5.1 The case of \mathcal{C}_3

Lemma 5.2 (rigidity and \mathcal{C}_3): *Let F be a bilinear function and suppose that the corresponding matrix has rigidity m^5 for rank m . Then, $\mathcal{C}_3(F) > m$.*

Proof: Suppose that $\mathfrak{C}_3(F) \leq m$, and consider a depth-three (general multi-linear) circuit C of arity m that computes F . Then, C has the form

$$C(x, y) = G(L_1(x), \dots, L_{m_1}, L'_1(y), \dots, L'_{m_2}(y), Q_1(x, y), \dots, Q_{m_3}(x, y)),$$

where G is a quadratic gate, $m_1 + m_2 + m_3 \leq m$, the $L_i(x)$'s and $L'_j(y)$'s are linear functions computable by depth-two circuits and the $Q_i(x, y)$'s are bilinear functions that are computed by depth-two circuits. Hence, for some $P \subseteq [m_1] \times [m_2]$ it holds that

$$C(x, y) = \sum_{(i,j) \in P} L_i(x)L'_j(y) + \sum_{i \in [m_3]} Q_i(x, y),$$

and each Q_i has the form

$$Q_i(x, y) = \sum_{(j,k) \in P_i} L_{i,j}(x)L'_{i,k}(y) + \sum_{j \in [t'_i]} Q_{i,j}(x, y),$$

where $P_i \subseteq [t_i] \times [t'_i]$ and $t''_i \leq m - (t_i + t'_i)$, and the $L_{i,j}(x)$'s and $L'_{i,k}(y)$'s are linear functions computable by depth-one circuits and the $Q_{i,j}(x, y)$'s are bilinear functions that are computed by depth-one circuits. Hence, the $L_{i,j}(x)$'s and $L'_{i,k}(y)$'s are linear gates and the $Q_{i,j}(x, y)$'s are bilinear gates (each taking m variables). Consider the matrix that corresponds to the function computed by Q_i . It is the sum of $|P_i| \leq t_i \cdot t'_i$ matrices of rank one, each being an outer product of two vectors that each has at most m one-entries, and t''_i matrices each having at most m^2 one-entries. Hence, the matrix that corresponds to $\sum_{i \in [m_3]} Q_i$ has sparsity at most $\sum_{i \in [m_3]} (t_i t'_i \cdot m^2 + t''_i \cdot m^2) \leq m^5$, since $m_3 \leq m$ and $t_i + t'_i + t''_i \leq m$. On the other hand, the matrix that corresponds to $\sum_{(i,j) \in P} L_i(x)L'_j(y)$ has rank $\min(m_1, m_2) < m$. It follows that the matrix that corresponds to F does not have rigidity m^5 for rank m . ■

Corollary 5.3 (a \mathfrak{C}_3 lower bound for random Toeplitz functions): *Almost all bilinear functions F that correspond to Toeplitz matrices satisfy $\mathfrak{C}_3(F) = \tilde{\Omega}(n^{0.4})$.*

Proof: Using Lemma 5.2 it suffices to show that F has rigidity m^5 for rank $m = \tilde{\Omega}(n^{0.4})$. This follows from special case of [3, Thm. 1.2], which asserts that a random Toeplitz matrix has rigidity $\Omega(n^2/\log n)$ for rank \sqrt{n} . ■

Corollary 5.4 (a \mathfrak{C}_3 lower bound for an explicit trilinear function): *The trilinear function $F(x, y, z) = \sum_{i,j \in [n]} x_i y_j z_{n+i-j}$ satisfies $\mathfrak{C}_3(F) = \tilde{\Omega}(n^{0.4})$.*

Proof: As in [2, 3], this follows from the existence of a bilinear function F' that corresponds to a Toeplitz matrix such that $\mathfrak{C}_3(F') = \tilde{\Omega}(n^{0.4})$ (cf. Corollary 5.3). ■

5.2 The case of $\mathfrak{C}^{(2)}$

Lemma 5.5 (rigidity and $\mathfrak{C}^{(2)}$): *Let F be a bilinear function and suppose that the corresponding matrix has rigidity m^4 for rank m^2 . Then, $\mathfrak{C}^{(2)}(F) \geq m$.*

Proof: Suppose that $\mathfrak{C}^{(2)}(F) \leq m - 1$, and consider a (general multi-linear) circuit C of arity $m - 1$ that has at most m^2 gates and computes F . We call a bilinear gate **mixed** if it fed both by bilinear gates and by either linear gates or variables, and call it a **terminal** if it is fed by linear gates and/or

Figure 1: Eliminating mixed gates. The bilinear gates are depicted by squares, and the auxiliary gate is filled. The triangles represent linear gates or variables.

variables only. We first get rid of mixed gates by introducing, for each mixed gate M , an auxiliary bilinear gate that “take over” the linear gates and variables that feed M , and feeds M instead (see Figure 1). The resulting number of terminal gates is at most m^2 , because each new terminal gate (i.e., a terminal gate introduced by the foregoing process) can be charged to a non-terminal bilinear gate in the original circuit. Hence, all the bilinear gates in C are terminal gates, and so C is the sum of these gates, denoted G_i for $i \in [m^2]$; that is,

$$C(x, y) = \sum_{i \in [m^2]} G_i(x, y),$$

where each G_i is fed by $m - 1$ linear gates and variables. Considering the sets of linear gates that feed into each of the G_i 's, we stress that *these sets are all subsets of a set of at most m^2 linear gates*, since C has at most this number of gates. That is, $G_i(x, y)$ takes the sum of some products of pairs of linear gates and variables; specifically, each product takes one element from $S_i \cup V_i$ and one element from $S'_i \cup V'_i$, where $S_i \subseteq [m^2]$ (resp., $S'_i \subseteq [m^2]$) represents the set of linear gates in x (resp., in y) that feed G_i , and $V_i \subseteq [n]$ (resp., $V'_i \subseteq [n]$) denotes the set of x -variables (resp., y -variables) that feed G_i . Recall that $|S_i| + |S'_i| + |V_i| + |V'_i| \leq m - 1$. Hence, G_i has the form

$$G_i(x, y) = \sum_{j \in S_i} L_j(x) M'_{i,j}(y) + \sum_{j \in S'_i} M_{i,j}(x) L'_j(y) + \sum_{(j,k) \in P_i \subseteq V_i \times V'_i} x_j y_k,$$

where the $L_j(x)$'s and $L'_j(y)$'s are linear gates of C , and the $M_{i,j}(x)$'s and $M'_{i,j}(y)$'s are arbitrary linear functions (which may depend on i). Specifically, $M_{i,j}(x)$ (resp., $M'_{i,j}(y)$) is a partial sum of $\sum_{k \in S_i} L_k(x) + \sum_{k \in V_i} x_k$ (resp., $\sum_{k \in S'_i} L_k(y) + \sum_{k \in V'_i} y_k$), where these partial sums are determined by G_i . Hence, assuming (w.l.o.g.) that $\cup_{i \in [m^2]} S_i = [m']$ (and $\cup_{i \in [m^2]} S'_i = [m' + 1, m^2]$), we can express C as

$$\begin{aligned} C(x, y) &= \sum_{i \in [m^2]} \left(\sum_{j \in S_i} L_j(x) M'_{i,j}(y) + \sum_{j \in S'_i} M_{i,j}(x) L'_j(y) + \sum_{(j,k) \in P_i \subseteq V_i \times V'_i} x_j y_k \right) \\ &= \sum_{j \in [m']} L_j(x) M'_j(y) + \sum_{j \in [m'+1, m^2]} M_j(x) L'_j(y) + \sum_{(j,k) \in P} x_j y_k, \end{aligned}$$

where $M'_j(x) = \sum_{i \in [m^2]} M'_{i,j}(x)$ (resp., $M_j(y) = \sum_{i \in [m^2]} M_{i,j}(y)$) and P is the multi-set consisting of $\cup_{i \in [m^2]} P_i$. Recalling that $|P_i| \leq |V_i| \cdot |V'_i| \leq (m - 1)^2$, it follows that the matrix corresponding to the function computed by C is the sum of two matrices of ranks m' and $m^2 - m'$, respectively,

and a matrix of sparsity $m^2 \cdot (m - 1)^2$. That is, this matrix does not have rigidity m^4 for rank m^2 . ■

Corollary 5.6 (an $\mathcal{C}^{(2)}$ lower bound for random Toeplitz functions): *Almost all bilinear functions F that correspond to Toeplitz matrices satisfy $\mathcal{C}^{(2)}(F) = \tilde{\Omega}(n^{3/8})$.*

Proof: Using Lemma 5.5 it suffices to show that F has rigidity m^4 for rank m^2 , where $m = \tilde{\Omega}(n^{3/8})$. This follows from [3, Thm. 1.2], which asserts that a random Toeplitz matrix has rigidity $\Omega(n^3/r^2 \log n)$ for rank $r > \sqrt{n}$. Specifically, using $r = m^2 = \tilde{\Omega}(n^{6/8})$, we get rigidity $\Omega(n^3/r^2 \log n) \geq m^4$, provided $\Omega(n^3/\log n) \geq m^8$. ■

Corollary 5.7 (an $\mathcal{C}^{(2)}$ lower bound for an explicit trilinear function): *The trilinear function $F(x, y, z) = \sum_{i,j \in [n]} x_i y_j z_{n+i-j}$ satisfies $\mathcal{C}^{(2)}(F) = \tilde{\Omega}(n^{3/8})$.*

Proof: As in [2, 3] (and Corollary 5.4), this follows from the existence of a bilinear function F' that corresponds to Toeplitz matrices such that $\mathcal{C}_3(F') = \tilde{\Omega}(n^{3/8})$ (cf. Corollary 5.6). ■

6 Better Lower Bounds on other Explicit Functions

Recall that Corollaries 5.3 and 5.6 establish that *almost all bilinear functions F that correspond to Toeplitz matrices satisfy $\mathcal{C}_3(F) = \tilde{\Omega}(n^{0.4})$ and $\mathcal{C}^{(2)}(F) = \tilde{\Omega}(n^{3/8})$* . In this section we get improved bounds for function that belong to any set of $\exp(-n)$ -biased space: Specifically, *almost all bilinear functions F whose coefficients are taken from an 2^{-n} -biased space satisfy $\mathcal{C}_3(F) = \tilde{\Omega}(n^{4/9})$ as well as $\mathcal{C}^{(2)}(F) = \tilde{\Omega}(n^{0.4})$* . Recall that these results yield similar lower bounds for an explicit 4-linear function [3]. (We shall consider bilinear functions in the variables $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$, and 4-linear functions in the variables x, y and $(s', s'') \in \{0, 1\}^{O(n)+O(n)}$.)

Preliminaries. Recall the definition of an ε -biased distribution from [6].

Definition 6.1 (small-biased distribution): *A distribution X over $\{0, 1\}^N$ is said to be ε -biased if for every non-empty set $S \subseteq [N]$, it holds that*

$$\left| \mathbf{E}_{x \sim X} [(-1)^{\sum_{i \in S} x_i}] \right| \leq \varepsilon .$$

We shall use the following property of ε -biased distributions (implicit in [6]).

Claim 6.2 [1, Lem. 1]: *Let X be an ε -biased distribution over $\{0, 1\}^N$. Let ℓ_1, \dots, ℓ_t be linearly independent linear functions on x_1, \dots, x_N . Then, the probability that all linear functions evaluate to 0 on $x \sim X$ is at most $\varepsilon + 2^{-t}$.*

6.1 The case of \mathcal{C}_3

Here we use techniques that are similar to those used in [3], but the actual argument is different. We call the reader's attention to an argument at the end of Step 2 of the proof, where a union bound on too many values is avoided and the (linear equations satisfied by the) linear span of these values is considered instead.³

³This technique was used in [3].

Theorem 6.3 (a \mathbf{C}_3 lower bound for bilinear functions selected from a small-biased sample space): *Almost all bilinear functions F that correspond to matrices drawn from a 2^{-n} -biased distribution on $\mathbb{F}_2^{n \times n}$ satisfy $\mathbf{C}_3(F) \geq \tilde{\Omega}(n^{4/9})$.*

Proof: Let m and r be non-negative integer parameters smaller than n , which we will set later. Along the way, we shall assume a few inequalities on m and r , which we will eventually satisfy by appropriately choosing m and r .

Our proof will show that the matrices associated with bilinear circuits of arity at most m and depth 3 can be partitioned into at most $\tilde{O}(2^{n/2})$ families such that, for each family of matrices, there exists a system of $r^2/2$ (linearly independent) linear equations in the matrix entries, that all matrices in the family satisfy. We will finish the proof by showing that most matrices drawn from a 2^{-n} -biased distribution on $\{0, 1\}^{n^2}$ do not belong to any of these families, and hence cannot be computed by a bilinear depth-3 circuits of arity at most m .

Step 1: Classifying matrices to families. We start by classifying all matrices associated with bilinear functions F that satisfy $\mathbf{C}_3(F) \leq m$ into families of matrices, each satisfying a system of $r^2/2$ linear equations. Consider a depth-three (general multi-linear) circuit C of arity m that computes F . As in Lemma 5.2, a generic C has the form

$$C(x, y) = \sum_{(i,j) \in [m] \times [m]} p_{i,j} \cdot \left(\sum_{\ell \in L_i} x_\ell \right) \cdot \left(\sum_{\ell \in L'_j} y_\ell \right) + \sum_{i \in [m]} Q_i(x, y),$$

where $P^{(0)} = (p_{i,j})_{i,j \in [m]} \in \{0, 1\}^{m \times m}$, the L_i 's and L'_j 's are subsets of size at most m^2 of $[n]$, and

$$Q_i(x, y) = \sum_{(j,k) \in [m] \times [m]} p_{j,k}^{(i)} \cdot \left(\sum_{\ell \in L_{i,j}} x_\ell \right) \cdot \left(\sum_{\ell \in L'_{i,k}} y_\ell \right) + \sum_{j \in [m]} Q_{i,j}(x, y),$$

where $P^{(i)} = (p_{j,k}^{(i)})_{j,k \in [m]} \in \{0, 1\}^{m \times m}$, the $L_{i,j}$'s and $L'_{i,k}$'s are subsets of size at most m of $[n]$, and the $Q_{i,j}(x, y)$'s are bilinear gates (each taking m variables).

To be more precise, for each $Q_{i,j}$, we associate two subsets $S^{(i,j)}, T^{(i,j)} \subseteq [n]$ corresponding to the indices of the x and y input variables of $Q_{i,j}$, respectively. We require $|S^{(i,j)}| + |T^{(i,j)}| \leq m$ and write $Q_{i,j}$ as

$$Q_{i,j}(x, y) = \sum_{k \in S^{(i,j)}} \sum_{\ell \in T^{(i,j)}} c_{i,j,k,\ell} \cdot x_k \cdot y_\ell \quad (2)$$

where $c_{i,j,k,\ell}$ are coefficients in $\{0, 1\}$ (defined for any $k \in S^{(i,j)}, \ell \in T^{(i,j)}$).

Hence, a concrete depth-three (general multi-linear) circuit C of arity m is specified in terms of the foregoing generic description by specifying the sets $L_i, L'_i, L_{i,j}, L'_{i,j}$ and $S^{(i,j)}, T^{(i,j)}$, hereafter called the **variable wiring** (or **wiring**), as well as the $m+1$ matrices $P^{(i)}$'s (for $i = 0, 1, \dots, m$) and the coefficients $c_{i,j,k,\ell}$'s, hereafter called the **bilinear forms**. Without loss of generality, we may envision C as a *formula* (i.e., a tree), and the sequence of sets as its leaves. This formula has at most $5m^3$ leaves (i.e., $\sum_{i \in [m]} (|L_i| + |L'_i|) + \sum_{i,j \in [m]} (|L_{i,j}| + |L'_{i,j}| + |S^{(i,j)}| + |T^{(i,j)}|) \leq 5m^3$), each labeled with a variable from $x_1, \dots, x_n, y_1, \dots, y_n$.

Let r be an integer and assume (for simplicity) that r divides n . We partition the x variables into n/r buckets, and similarly we partition the y variables. Specifically, for $a, b \in [n/r]$, let $X_a := \{x_{(a-1)r+1}, x_{(a-1)r+2}, \dots, x_{ar}\}$ be the a^{th} bucket of the x variables, and let $Y_b := \{y_{(b-1)r+1}, y_{(b-1)r+2}, \dots, y_{br}\}$ be the b^{th} bucket of the y variables. For a fixed variable wiring, we call a bucket-pair (X_a, Y_b) **typical** if the following three conditions hold:

1. At most $50 \cdot m^3 \cdot r/n$ of the leaves in the formula are labeled with variables from X_a .
2. At most $50 \cdot m^3 \cdot r/n$ of the leaves in the formula are labeled with variables from Y_b .
3. There are at most $10 \cdot m^4 \cdot r^2/n^2$ quadruples (i, j, k, ℓ) such that $(x_k, y_\ell) \in X_a \times Y_b$ and x_k and y_ℓ are inputs to $Q_{i,j}$. (i.e., $k \in S^{(i,j)}$ and $\ell \in T^{(i,j)}$).

Observing that a random bucket-pair (X_a, Y_b) satisfies each condition (individually) with probability at least 0.9, it follows that most bucket-pairs satisfy all conditions simultaneously. Hence, for each wiring, most bucket-pairs (X_a, Y_b) are typical.

For each pair $(a, b) \in [n/r]$, we consider all wirings for which (X_a, Y_b) is typical. Actually, it suffices to consider a partial wiring that specifies only the placing/wiring of variables in $X_a \cup Y_b$. To specify such a partial wiring it suffices to specify which of these variables appears in which leaf of the formula; that is, assign a variable of X_a (resp., Y_b) to at most $10m^3r/n$ of the leaves. Hence, we have at most $\binom{5m^3}{50m^3r/n} \cdot (|X_a| + 1)^{50m^3r/n} < (n^4)^{50m^3r/n}$ possibilities for wiring of variables in X_a , and ditto for Y_b . Thus, there are at most $(n^4)^{100 \cdot m^3 \cdot r/n}$ possible wirings for all variables in $X_a \cup Y_b$ to the gates that read them. We shall assume

$$100 \cdot m^3 \cdot \frac{r}{n} \leq \frac{n}{10 \cdot \log n} \quad (3)$$

giving us at most $(n^4)^{n/10 \log n} \leq 2^{n/2}$ possible wirings.

We partition all bilinear functions F with $\mathcal{C}_3(F) \leq m$ to families according to a choice of a bucket-pair (X_a, Y_b) and a partial wiring of $X_a \cup Y_b$ such that (X_b, Y_b) is typical for this wiring. This gives us an upper bound of $(n/r)^2 \cdot 2^{n/2}$ on the number of families.

Step 2: Associating a system of linear equations with each family of matrices. We consider a fixed family of matrices; that is, we fix a choice of a bucket-pair (X_a, Y_b) and a choice of wirings of $X_a \cup Y_b$ for which the said pair is typical. We focus on the r -by- r submatrices of the matrices in the family whose rows correspond to variables in X_a and columns correspond to variables in Y_b .

For every (k, ℓ) such that $x_k \in X_a$ and $y_\ell \in Y_b$, we consider how the (k, ℓ) -th entry of the matrices in the family looks like. Note that the (k, ℓ) -th entry in the matrix corresponding to the bilinear function equals the value of the bilinear function on the input with all zeros except for x_k and y_ℓ . Now, for a fixed family, since the wirings of X_a and Y_b are fixed, the (k, ℓ) -th entry is a *fixed* linear combination in the entries of $P^{(i)}$'s (with $i \in \{0, 1, \dots, m\}$) and the relevant coefficients $c_{i,j,k,\ell}$, where the relevant coefficients $c_{i,j,k,\ell}$ are those for which $k \in S^{(i,j)}$ and $\ell \in T^{(i,j)}$. Thus, all entries in the r -by- r submatrix corresponding to $X_a \times Y_b$ are fixed linear combinations in the entries of $P^{(i)}$'s and the relevant coefficients $c_{i,j,k,\ell}$. There are at most $(m+1) \cdot m^2$ entries in the $P^{(i)}$'s, and at most $10 \cdot m^4 \cdot r^2/n^2$ relevant coefficients $c_{i,j,k,\ell}$ (by Property 3 of a typical bucket-pair). Assuming that

$$(m+1) \cdot m^2 + 10 \cdot m^4 \cdot \frac{r^2}{n^2} \leq \frac{r^2}{2} \quad (4)$$

this means that the r^2 entries of a submatrix in a generic matrix in the family are fixed linear combinations of at most $r^2/2$ values (i.e., the entries of $P^{(i)}$'s and the relevant coefficients $c_{i,j,k,\ell}$). Hence, these r^2 entries must satisfy a fixed system of at least $r^2/2$ independent linear equations, since each entry is a fixed linear combination of at most $r^2/2$ values.⁴

⁴Formally, we can write each of the r^2 entries as a fixed linear combination of at most $r^2/2$ symbolic variables. Viewing these r^2 entries as an r^2 -dimensional vector, we note that this vector must reside in a fixed vector space of dimension at most $r^2/2$ over \mathbb{F}_2 , which in turn can be characterized by a fixed system of at least $r^2/2$ independent linear equations.

Step 3: Showing that, whp, small-biased matrices do not belong to any of the families. To finish, we show that a matrix drawn from a 2^{-n} -biased distribution is unlikely to be a member in any of these $2^{n/2} \cdot (n/r)^2$ families of matrices. For a fixed family, we calculate the probability that a matrix B drawn from a 2^{-n} -biased distribution belongs to this family, and then take a union bound over all families. To be included in a fixed family, the matrix B should satisfy at least $r^2/2$ specific independent linear equations. By Claim 6.2, this happens with probability at most $2^{-n} + 2^{-r^2/2} \leq 2 \cdot 2^{-n}$ assuming $r \geq \sqrt{2n}$. We are left to pick r and m while satisfying Eq. (3), Eq. (4), and $r \geq \sqrt{2n}$. The choice

$$r \stackrel{\text{def}}{=} \frac{n^{2/3}}{6 \cdot \log^{1/3}(n)} \quad \text{and} \quad m \stackrel{\text{def}}{=} \frac{n^{4/9}}{6 \cdot \log^{2/9}(n)} = \Theta(r^{2/3})$$

satisfies all of the above, assuming n is large enough. Under this choice of parameters (and using a union bound), the probability that the bilinear function F_B associated with a matrix B , drawn from a 2^{-n} -biased distribution, satisfies $\mathcal{C}_3(F_B) \leq m$ is at most $(2^{n/2} \cdot (n/r)^2) \cdot (2 \cdot 2^{-n}) \leq 2^{-\Omega(n)}$. ■

Corollary 6.4 (a \mathcal{C}_3 lower bound for an explicit 4-linear function): *There exists an explicit bilinear function $G : \{0, 1\}^{O(n)+O(n)} \rightarrow \{0, 1\}^{n^2}$ such that the 4-linear function $F(x, y, s', s'') = \sum_{i,j \in [n]} G(s', s'')_{i,j} x_i y_j$ satisfies $\mathcal{C}_3(F) = \tilde{\Omega}(n^{4/9})$.*

Proof: As in [3], this follows by combining Theorem 6.3 with a construction of a small-biased generator $G : \{0, 1\}^{O(n)+O(n)} \rightarrow \{0, 1\}^{n^2}$ that is a bilinear function (see [5]). By Theorem 6.3, for most settings of $s = (s', s'')$, it holds that the resulting bilinear function $F'(x, y) = \sum_{i,j \in [n]} G(s', s'')_{i,j} x_i y_j$ satisfies $\mathcal{C}_3(F') = \tilde{\Omega}(n^{4/9})$, whereas $\mathcal{C}_3(F) \geq \mathcal{C}_3(F')$. Observing that F is 4-linear, the claim follows. ■

6.2 The case of $\mathcal{C}^{(2)}$

We mention that following the proof in [3], one can get $\mathcal{C}^{(2)}(F) = \tilde{\Omega}(n^{0.4})$ for F as in Theorem 6.3 and Corollary 6.4. We do not present the proof here, since it basically amount to reproducing large portions of [3] (i.e., [3, Sec. 4] and [3, Sec. 5.1]), without any new ideas or techniques. The only difference would have been decoupling the number of gates from the arity, and using these two parameters rather than one. Specifically, we have

Theorem 6.5 ([3, Thm. 5.6], revised by decoupling size and arity):⁵ *Let A be an n -by- n matrix A whose entries are sampled from an ε -biased distribution. Then, the corresponding bilinear function can be computed by a bilinear circuit of arity m and size s with probability at most*

$$\left(\frac{n}{2s}\right)^2 \cdot \left(\leq 12s^2 m/n\right)^4 \cdot \left(\varepsilon + 2^{-s^2+24s^3 m^2/n^2}\right).$$

In particular, using $s = m^2 > \sqrt{n}$ and $\varepsilon = 2^{-n}$, we get a probability bound of $\exp(\tilde{O}(m^5/n)) - \min(n, m^4 - O(m^8/n^2))$. Hence, with high probability, the bilinear function F_A associated with a matrix A whose entries are sampled from an ε -biased distribution, satisfies $\mathcal{C}^{(2)}(F_A) = \tilde{\Omega}(n^{0.4})$.

⁵Indeed, in [3, Thm. 5.6], $s = m$.

7 Depth Reductions

In this section, we show connections between $\mathbf{C}_d(\cdot)$ for different depths d . First, we show a simple connection between $\mathbf{C}_{kd}(\cdot)$ and $\mathbf{C}_d(\cdot)$ for any $k \in \mathbb{N}$. As a special case, we get $\mathbf{C}_{2k}(F) \geq \mathbf{C}_2(F)^{1/k}$. Next, we show a less clean connection between $\mathbf{C}_{2k+1}(F)$ and $\mathbf{C}_2(F)$. We note that establishing connections between $\mathbf{C}^{(e)}(\cdot)$ for different values of e remains open.

Lemma 7.1 (depth reduction – simple case): *For any multilinear function F and $d, k \in \mathbb{N}$, it holds that*

$$\mathbf{C}_d(F) \leq \mathbf{C}_{kd}(F)^k.$$

As a special case, we get $\mathbf{C}_d(F) \geq \mathbf{C}_2(F)^{2/d}$ for every even depth d . Hence, *any non-trivial lower bound for depth 2 implies a non-trivial lower bound for every even depth d* , where a non-trivial lower bound for depth d refers to any lower bound of the form $\mathbf{C}_d(F) = \omega((tn)^{1/d})$ (for a t -linear function F). This terminology is justified by the fact that a lower bound of the form $\mathbf{C}_d(F) = \Omega((tn)^{1/d})$ holds trivially for any t -linear function F that depends on all its tn input variables (because otherwise the multilinear circuit cannot even read all the input bits).

Proof Sketch: Starting with any multilinear circuit for F having depth kd and arity $m = \mathbf{C}_{kd}(F)$, collapse every k consecutive layers into one layer, resulting in a t -linear circuit of depth d and arity m^k . Hence, $\mathbf{C}_d(F) \leq \mathbf{C}_{kd}(F)^k$. ■

Since we have non-trivial lower bounds for depth 2, we get from Lemma 7.1 non-trivial lower bounds on $\mathbf{C}_d(F)$ for any even d (see the discussion after Lemma 7.2 for specific details). We would like to get a similar result for odd depths, but the straightforward approach gives $\mathbf{C}_d(F) \geq \mathbf{C}_{d+1}(F) \geq \mathbf{C}_2(F)^{2/(d+1)}$ for every odd d . While this implies non-trivial lower bounds on $\mathbf{C}_d(F)$ for all sufficiently large odd d , it currently yields trivial bounds for small d (e.g., $d = 3$). Specifically, the best lower bound known on an explicit function F asserts $\mathbf{C}_2(F) = \tilde{\Omega}(n^{2/3})$, which implies only the trivial bound of $\mathbf{C}_3(F) = \tilde{\Omega}(n^{1/3})$.

Lemma 7.2 (depth reduction – odd depths to depth 2): *Let $k \in \mathbb{N}$. Then, for any t -linear function F , it holds that*

$$\mathbf{C}_2(F) \leq O(\mathbf{C}_{2k+1}(F)^{k+(t/(t+1))}).$$

It seems that the ideas underlying the following proof may work to reduce depth d to depth $d' < d$ in general (i.e., when d' may not divide d). However, due to the lack of applications for such a general reduction, we decided to focus on the case $d' = 2$.

Proof Sketch: The main idea is to first split the middle layer into two layers of smaller arity using [2, Thm. 3.1], and then collapse the top $k + 1$ (resp., the bottom $k + 1$) layers into one layer. Specifically, using [2, Thm. 3.1] (alternatively Theorem 4.1), split each gate in layer $k + 1$ to an equivalent sub-circuit with two layers and arity $O(m)^{t/(t+1)}$. After the split, the circuit has $2k + 2$ layers, where the first k layers have gates of arity at most m , the next two layers have gates of arity at most $O(m)^{t/(t+1)}$, and the last k layers have gates with arity at most m . Collapsing the first $k + 1$ layers and the last $k + 1$ layers, results in a multilinear circuit of depth 2 and arity $O(m^{k+(t/(t+1))})$ computing F . Thus, $\mathbf{C}_2(F) = O(\mathbf{C}_d(F)^{k+(t/(t+1))})$ as required. ■

Corollaries. We use the lower bound from [3, Thm. 1.5], which asserts that the bilinear function associated with a random Toeplitz matrix has $\mathbf{C}_2(F) = \Omega(n^{2/3})$, with high probability (over the random choices of the $2n - 1$ values along the diagonals). Using Lemma 7.1, we get the non-trivial

lower bound $\mathcal{C}_d(F) = \tilde{\Omega}(n^{4/(3d)})$ for even depths d . For odd depths $d = 2k + 1$, we use Lemma 7.2 to get the non-trivial lower bound

$$\mathcal{C}_d(F) = \tilde{\Omega}\left(n^{\frac{2/3}{k + (t/(t+1))}}\right) = \tilde{\Omega}\left(n^{4/(3d+1)}\right),$$

where the second equality uses the fact that $t = 2$ and $d = 2k + 1$. As in [2, 3] (and Corollary 5.4), these lower bounds for random Toeplitz matrices imply a similar lower bound for an explicit *trilinear* function.

Corollary 7.3 (a \mathcal{C}_d lower bound for an explicit trilinear function): *The trilinear function $F(x, y, z) = \sum_{i,j \in [n]} x_i y_j z_{n+i-j}$ satisfies $\mathcal{C}_d(F) = \tilde{\Omega}(n^{4/(3d)})$ for even d and $\mathcal{C}_d(F) = \tilde{\Omega}(n^{4/(3d+1)})$ for odd d .*

In particular, we get $\mathcal{C}_3(F) = \tilde{\Omega}(n^{0.4})$, just as in Corollary 5.4. In light of the above, it may seem that Section 5.1 is redundant. However, on top of serving as a warmup for Sections 5.2 and 6.1, the contents Section 5.1 is not exhausted by Corollary 5.4, since it offers a structural result for matrices associated with low-complexity depth-3 bilinear circuits (i.e., Lemma 5.2). Furthermore, the proof in Section 5.1 relies on a rigidity lower bound of [3, Thm. 1.2], whereas Corollary 7.3 relies on a larger lower bound on “structured rigidity” provided by [3, Thm. 1.5] via a more complex proof.
