Abstract

Given the polygonal schema embedding of an $O(\log n)$ genus graph $G$ and two vertices $s$ and $t$ in $G$, we show that deciding if there is a path from $s$ to $t$ in $G$ is in unambiguous logarithmic space.
1 Introduction

Deciding reachability between a pair of vertices is an important problem in computational complexity theory. Directed graph reachability characterizes the complexity of the class nondeterministic logspace (NL) and undirected graph reachability characterizes the complexity of the class deterministic logspace (L). The latter follows due to a seminal result by Reingold in 2005 [19]. Several other variants of this problem characterize the complexity of other complexity classes [11, 5, 6].

Unambiguous computations are a natural restriction of nondeterministic computation where for every input the Turing machine can have at most one accepting computation path. In the domain of logarithmic space, this defines the class unambiguous logspace (UL) of languages for which there is a nondeterministic logspace bounded machine that has exactly one accepting path for every input in the language and zero accepting path otherwise. The class UL was introduced in [8] and subsequently its properties were also studied in the paper [3]. The relation between NL and UL was not well understood till that point. In 1997, Reinhardt and Allender showed that NL and UL are equal in a non-uniform setting [20]. Subsequently, it was shown that if deterministic linear space functions cannot be computed by $2^n$ sized circuits then NL = UL [2]. Both these results gave evidence that most likely the classes were the same unconditionally. Recently directed graph reachability was shown to be decidable by an unambiguous algorithm running in polynomial time and using $O(\log^2 n)$ space [15]. The space bound was improved to $O(\log^{1.5} n)$ in a subsequent result [24].

A graph $G$ is said to be min-unique with respect to a weight function $w$ if for every pair of vertices in $G$ there is at most one minimum weight path from one vertex to the other with respect to $w$. We will call such a weight function a path isolating weight function. Min-uniqueness has been studied in several papers [25, 13, 20]. Reinhardt and Allender showed that if graphs in a class of graphs are min-unique with respect to an $O(\log n)$ bit weight function then deciding reachability for that class of graphs is in UL [20]. They also gave a UL algorithm to check if a graph is min-unique.

Observe that devising a UL algorithm for directed graph reachability would show that NL = UL, since directed graph reachability is complete for the class NL. Although the NL versus UL has been elusive so far, partial progress has been made towards solving this problem. For several classes of directed graphs, the reachability problem has been shown to be in UL – such as layered grid graphs [1], planar graphs [7], constant genus graphs [16, 10], graphs with polynomially many paths from the source to all other vertices [18], $K_{3,3}$-free and $K_5$-free graphs [22, 4]. The techniques involve either an efficient construction of a path isolating weight function or reduction to reachability in a graph class for which the problem is already known to be in UL.

Reachability in positive genus graphs is a natural extension of planar reachability. Allender et al. showed that reachability in genus 1 graphs can be reduced to planar reachability [1]. After planar reachability was shown to be in UL, reachability in constant genus graphs was reduced to reachability in planar graphs [16]. Later a path isolating weight function was also given for constant genus graphs [10]. Prior to our result, the best known nondeterministic space upper bound for reachability in non-constant genus graphs was nothing better than general directed graphs. The question of whether reachability in $\omega(1)$ genus graphs belongs to UL or not has been open for almost a decade.

1.1 Our Result

In this paper, we make progress towards understanding the space complexity of directed graph reachability and show the following result.
Theorem 1. Given a polygonal schema of an $O(\log n)$ genus directed graph $G$, deciding reachability in $G$ is in $\text{UL} \cap \text{coUL}$.

Given a genus $g$ graph, in the first stage, we give an $O(\log n)$ bit weight function $w_{pl}$ which is essentially the same weight function as defined in [21] and another weight function $w_{len}$ which gives weight 1 to every edge in the graph. Weight function $w_{len}$ ensures that minimum weight paths among all pairs of vertices are of minimum length as well. We then show that between every pair of vertices in the graph, the number of minimum weight “topologically unequivalent” paths is at most $2^{O(g)}$. For this, we define a notion called signature which allows us to classify topologically equivalent paths. We show that topologically equivalent paths are very similar to paths in planar graphs and therefore we can borrow the machinery for path isolation in planar graphs here as well. In the second stage, we use the hashing scheme of Fredman, Komlós and Szemerédi [12] to compute an $O(\log n + g)$ bit weight function $w_{fks}$ with respect to which only one among the $2^{O(g)}$ many paths of the first stage gets the minimum weight value.

When $g$ is $O(\log n)$ the number of such minimum weight paths produced in the first stage is at most polynomial in $n$. Thereafter by combining the weight functions $w_{len}$, $w_{pl}$ and $w_{fks}$ we get an $O(\log n)$ bit weight function with respect to which the graph is min-unique. We then apply Reinhardt and Allender’s algorithm to get a $\text{UL}$ algorithm for $O(\log n)$ genus reachability.

1.2 Organization of the Paper

The rest of the paper is organized as follows. In Section 2 we define the notations and framework of our problem. We discuss different representations of high genus graphs and how to efficiently obtain a representation that is suitable for our purpose. We also state results from earlier work that we use in this paper. In Section 3 we prove the main result by giving a min-unique weight function.

2 Preliminaries

Let $G = (V, E)$ be a directed graph on $n$ vertices and $m$ edges. Let $uv$ denote an edge directed from $u$ to $v$. A weight function is a map $w : E \to \mathbb{Z}$ which maps every edge in $G$ to an integer. A weight function $w$ is said to be skew-symmetric if for every edge $uv$, $w(uv) = -w(vu)$. For a set of edges $S$, $w(S) = \sum_{e \in S} w(e)$. We can think of different structures in a graph such as path, walk, cycle as sets of edges and define the weight of the structure accordingly.

2.1 Representation of High Genus Graph

A genus $g$ surface is a sphere with $g$ handles on it. The genus of a graph is the minimum genus surface on which the graph can be embedded without any edge crossings. Such an embedding is also called a 2-cell embedding. Since we are dealing with graphs embedded on surfaces, it is important to specify how the input graph is represented. Given a graph, computing its genus is NP-hard [23]. To the best of our knowledge, no PTAS is known either to compute the genus of a graph. So in accordance with the convention followed by earlier papers that deals with problems on bounded genus graphs, we also assume a suitable representation of the input graph [17, 14]. We use a representation similar to the one used by Mahajan and Varadarajan [17].

Given a genus $g$ graph $G$ we consider an embedding of $G$ inside a polygon $S$ with $4g$ sides, $s_1, s_2, \ldots, s_{4g}$. We refer to these as the segments of $S$. Moreover, we assume there is no vertex on the boundary of the polygon. The segments $s_{4k+1}$ and $s_{4k+2}$ are directed in anti-clockwise and segments $s_{4k+3}$ and $s_{4k+4}$ are directed in clockwise direction. The segments $s_{4k+1}$ and $s_{4k+3}$
form a pair together such that an edge can come into one of them and go out from another. Similarly, segments $s_{4k+2}$ and $s_{4k+4}$ form a pair. Also, if an edge is the $j$th edge crossing a segment $s_i$ from head to tail then it will be the $j$th edge crossing the paired segment of $s_i$ from tail to head. Pairs $(s_{4k+1}, s_{4k+3})$ and $(s_{4k+2}, s_{4k+4})$ together constitute the $i$th handle of the sphere. We assume that we are provided with the combinatorial embedding of the graph $G$ inside $S$ and an ordering of the edges crossing each segment $s_i$. We also assume without loss of generality that an edge can cross a segment of the polygonal schema at most once, as an edge crossing multiple segments can be divided into several edges in logspace so that the assumption is true. We call this representation the polygonal schema of $G$.

Let $E_S$ be the set of edges in $G$ that cross some segment $s_i$. Then observe that $G_{\text{planar}} = G \setminus E_S$ is a planar graph. A piecewise straight line embedding of a planar graph is an embedding where vertices are integral coordinates and an edge is a piecewise straight line segment connecting its two end points such that no two edges intersect. Given the combinatorial embedding of a planar graph a piecewise straight line embedding of it can be constructed in logspace such that each edge consists of at most 4 segments [21].

For a genus $g$ graph $G$, a flat schema is an embedding of $G$ such that the polygon $S$ is represented as a straight line segment parallel to the $x$-axis, the internal planar graph $G_{\text{planar}}$ is given as a piecewise straight line embedding and each edge in $E_S$ is drawn as a piecewise straight line segment such that no two edges cross each other. Moreover, all vertices and points where an edge crosses a segment are integral coordinates. See Figure 1 for an example of a flat schema of $K_5$.

![Figure 1: Embeddings of $K_5$](image)

Given a polygonal schema of $G$, we can compute a piecewise straight line embedding of $G_{\text{planar}}$ in logspace. Now using a similar idea we draw each edge in $E_S$ as a piecewise straight line segment from its end vertices to the corresponding segments of $S$. We summarize this process in Lemma 2.

**Lemma 2.** Given a polygonal schema of a graph $G$ with $4g$ segments we can construct a flat schema of $G$ with $4g$ segments in logspace.

The weight function $w_{pl}$ that we define in Section 3 is similar to the weight function in [21]. That is why we need edges to be piecewise straight line segments. Also the flat schema embedding is necessary because we want all edges parallel to the $x$-axis to have weight 0 with respect to $w_{pl}$.

### 2.2 Previous Work

Consider a genus $g$ graph $G$ embedded on a surface of genus $g$ say $\Gamma$. A simple cycle $C$ in $G$ is called a *separating cycle* if cutting along $C$ divides the surface into at least two parts. Otherwise
C is called a non-separating cycle. We state a characterization of these cycles from Lemma 4 of Cabello and Mohar [9] and Lemma 10 of Datta et al. [10].

**Theorem 3.** [9, 10] Consider a polygonal schema of a genus g graph. A cycle C in G is said to be surface separating if and only if C crosses each segment of the polygonal schema an even number of times. Moreover, if C is surface separating then with respect to each segment s_i, the cycle C alternates between coming into s_i and going out of it (if C crosses s_i at all).

We next state the popular hashing result by Fredman, Komlós and Szemerédi.

**Theorem 4.** [12] Let S = \{x_1, x_2, ..., x_k\} be a set of n−bit integers. Then there exists an O(\log n + \log k) bit prime number p so that for all x_i ≠ x_j ∈ S, x_i mod p ≠ x_j mod p.

In Theorem 5 we state a slightly modified version of Reinhardt and Allender’s result that would be useful for our purpose.

**Theorem 5.** [20] There is a nondeterministic logspace Turing machine M that takes a tuple (G, s, t, w) as input where G is a directed graph on n vertices, s and t are vertices in G and w is an O(\log n) bit edge weight function and outputs the following along a unique computation path while all other computation paths halt and reject:

- Not Min-unique if G is not min-unique with respect to w,
- Yes if G is min-unique with respect to w and there is a path from s to t in G, and
- No if G is min-unique with respect to w and there is no path from s to t in G.

Finally, in Theorem 6 we state the relation between the area of a simple cycle in a planar graph and weight of the cycle with respect to a suitable weight function as shown by Tewari and Vinodchandran.

**Theorem 6.** [21] Given a straight line embedding of a planar graph G there exists a logspace computable weight function w such that for any cycle C in G, we have w(C) = 2 · Area(C) if C is a counter-clockwise cycle and w(C) = −(2 · Area(C)) if C is a clockwise cycle, where Area(C) is the area of the region enclosed by C.

### 3 Isolating Paths in High Genus Graphs

In this section we show that graphs of logarithmic genus are min-unique with respect to an O(\log n)-bit weight function that can be computed by an unambiguous logspace machine. Using this weight function in combination with Theorem 5 we get a \(UL \cap coUL\) algorithm for directed graph reachability in O(\log n) genus graphs. Theorem 7 is the main technical result of this paper where we show the existence and computability of such a weight function.

**Theorem 7.** Given a genus g directed graph G = (V, E) in terms of its flat schema, there exists an O(\log n + g) bit weight function w : E → Z, such that for every u, v ∈ V, there exists a unique minimum weight path from u to v with respect to w, if v is reachable from u. Moreover, there is a nondeterministic O(\log n + g) space algorithm that given G as input, outputs the weight function w along a unique computation path while all other paths halt and reject.

Let S = \{s_1, s_2, ..., s_{4g}\} be the set of segments of the flat schema of G. We define a skew-symmetric weight function w_{pl} that gives non-zero weight to every surface separating cycle in G. For edges which do not cross any segment of the flat schema (we refer to them as planar edges),
$w_{pl}$ is same as the weight function defined in [21], and for edges which do cross some segment of the flat schema (we refer to them as crossing edges) we modify the weight function to be the sum of the weights of the two line segments of the edge. Formally, for an edge $e = uv$ we define the $w_{pl}(e)$ as:

$$w_{pl}(e) = \begin{cases} (y_u - y_u)(x_v + x_u) & \text{if } e \text{ is a planar edge} \\ (y_{uv} - y_u)(x_{uv} + x_u) + (y_v - y_{uv})(x_v + x_{uv}) & \text{if } e \text{ is a crossing edge} \end{cases}$$

where $(x_u, y_u)$ and $(x_{uv}, y_{uv})$ are the coordinates of $u$ and $v$ respectively and $(x_{uv}', y_{uv}')$ and $(x_v', y_v')$ are the coordinates of intersection points of edge $e$ with segments $s_i$ and $s_j$ respectively, assuming that edge $e$ comes into $s_i$ and goes out of $s_j$.

We also define another weight function $w_{len}$ that assigns value one to every edge in the graph. That is $w_{len}(e) = 1$ for every edge $e \in G$. Let $w_{comb} = w_{len} \cdot n^{k_1} + w_{pl}$ be the weight function defined by combining $w_{pl}$ and $w_{len}$ for a large enough constant $k_1$. As a result the minimum weight path with respect to $w_{comb}$ also has the minimum length.

We first show that every surface separating cycle has non-zero weight with respect to $w_{pl}$. The idea is to decompose every surface separating cycle into a set of planar cycles having the same orientation such that the weight of the original cycle is the sum of the weights of the planar cycles.

**Lemma 8.** Let $C$ be a simple surface separating cycle of length at least 3 in $G$, then $w_{pl}(C) \neq 0$.

**Proof.** A surface separating cycle can be of two types – one which does not intersect with any segment of the flat schema and the one which does. If $C$ does not intersect any segment of the flat schema then $C$ is a planar cycle. Hence $w_{pl}(C) \neq 0$ by [21].

Now consider the case where some edges of $C$ cross the flat schema. From Theorem 3 we know that since $C$ is a surface separating cycle, therefore, $C$ alternates between going out and coming into the segments of the flat schema. Without loss of generality assume that the first edge of $C$ crossing the flat schema going left to right, is coming into it. The other case is analogous.

For every edge $uv$ which crosses the boundary $S$ of the flat schema we subdivide $uv$ into two directed edges $uw'$ and $v'v$, such that $w'$ is the point at which $uv$ comes into some segment $s_i$ and $v'$ is the point at which $uv$ goes out of some segment $s_j$. Let $C'$ be the cycle corresponding to $C$ formed by this subdivision. By definition of $w_{pl}$ we have $w_{pl}(uv) = w_{pl}(uw') + w_{pl}(v'v)$ and hence $w_{pl}(C) = w_{pl}(C')$.

Let $x_1, x_2, \ldots, x_{2t}$ be the set of intersection points of $C'$ and $S$ ordered from left to right. Add $t$ dummy directed edges from $x_{2i-1}$ to $x_{2i}$ for all $1 \leq i \leq t$. This decomposes $C'$ into a set of disjoint planar cycles $C_1, C_2, \ldots, C_t$ such that each $C_i$ has the same orientation (counter-clockwise, since we assume the first edge is coming into $S$). See Figure 2 for an example.

![Surface separating cycle C](image1.png)

![Decomposition of C into C1, C2 and C3](image2.png)

**Figure 2:** Decomposing a surface separating cycle into planar cycles

6
By Theorem 6, \( w_{pl}(C_i) = 2 \cdot \text{Area}(C_i) \) for each \( i \). Moreover, since the \( C_i \)'s have all the edges of \( C' \) plus some horizontal edges (the dummy edges) of zero weight, therefore \( w_{pl}(C') = \sum_{i=1}^{k} w_{pl}(C_i) = 2 \cdot \sum_{i=1}^{k} \text{Area}(C_i) \). Therefore \( w_{pl}(C) \neq 0 \). □

We now show that the number of minimum weight paths with respect to \( w_{comb} \), between any pair of vertices is at most \( 2^{2g} \). We define classes of paths based on the number of times a path intersects each segment of the flat schema, and show that in each such class there is at most one minimum weight path.

Given a polygonal schema of a genus \( g \) graph \( G \), by Lemma 2 we assume that we are provided with a flat schema of \( G \) having \( 4g \) segments. Let \( T = \{T_1, T_2, \ldots, T_{2g}\} \) be the set of segments of the flat schema such that no two elements of \( T \) are pairs of each other.

For a path \( P \) in \( G \), define the signature of \( P \), denoted as \( \text{sign}(P) \), as a binary string \( s = s_1s_2\ldots s_{2g} \) where \( s_i = 1 \) if \( P \) crosses \( T_i \) an odd number of times and \( s_i = 0 \) if \( P \) crosses \( T_i \) an even number of times. Clearly, the total number of different signatures are \( 2^{2g} \). This definition can be similarly extended to cycles and walks as well.

For \( 0 \leq i \leq 2^g - 1 \), let \( \text{bin}(i) \) be the \( l \)-bit string that denotes the binary representation of \( i \) (if the binary representation has less than \( l \) bits then we prefix it with appropriate number of zeroes to make it \( l \)-bit long). For every pair of vertices \( u \) and \( v \), we define \( 2^{2g} \) classes of paths \( K_{i*}, K_{*v}, K_{iv}, \ldots, K_{2^{2g}-1} \) as follows:

\[
K_{i*} = \{P \mid P \text{ is path from } u \text{ to } v \text{ and } \text{sign}(P) = \text{bin}(i)\}.
\]

Note that if \( P = P_1P_2\ldots P_k \) be a partition of a path \( P \) into subpaths, then \( \text{sign}(P) = \text{sign}(P_1) \oplus \text{sign}(P_2) \oplus \ldots \oplus \text{sign}(P_k) \), where \( \oplus \) is the bitwise XOR operator.

For a directed path \( P \) from \( x \) to \( y \), let \( P^r \) represent the directed path from vertex \( y \) to \( x \) obtained by reversing the edges along the path \( P \). Note that \( \text{sign}(P) = \text{sign}(P^r) \).

**Theorem 9.** Let \( G = (V, E) \) be a genus \( g \) graph embedded on a flat schema having \( 4g \) segments. Let \( u \) and \( v \) be two vertices in \( G \) and \( i \) be a non-negative integer less than or equal to \( 2^{2g} - 1 \). Then in every class \( K_{i*} \) there exists at most one minimum weight path from \( u \) to \( v \) with respect to \( w_{comb} \).

**Proof.** Assume that \( P_1 \) and \( P_2 \) are two minimum weight paths in \( K_{i*} \) with respect to \( w_{comb} \). Then \( w_{pl}(P_1) = w_{pl}(P_2) \) and \( w_{len}(P_1) = w_{len}(P_2) \). Consider two cases – when \( P_1 \) and \( P_2 \) have common intermediate vertices and when they do not.

**Case 1:** \( P_1 \) and \( P_2 \) do not have any common intermediate vertices

We will show that \( P_1 \) and \( P_2 \) together form a surface separating cycle. Let \( C = P_1P_2^r \) be the directed cycle formed by taking \( P_1 \) followed by \( P_2^r \). Since \( P_1 \) and \( P_2 \) do not have any common intermediate vertices therefore \( C \) is a simple cycle. Recall that \( w_{pl} \) is a skew-symmetric weight function so \( w_{pl}(P_2^r) = -w_{pl}(P_2) \). Therefore,

\[
\begin{align*}
    w_{pl}(C) &= w_{pl}(P_1) + w_{pl}(P_2^r) \\
               &= w_{pl}(P_1) - w_{pl}(P_2) \\
               &= 0 \quad \text{(since } P_1 \text{ and } P_2 \text{ have the same minimum weight)}
\end{align*}
\]

Also since \( P_1 \) and \( P_2 \) belong to \( K_{i*} \) we have that \( \text{sign}(P_1) = \text{sign}(P_2) = \text{sign}(P_2^r) \). Therefore we get that \( \text{sign}(C) = 0 \) (the all zeroes vector). By Theorem 3 we have that \( C \) is a surface separating cycle and thus by Lemma 8 \( w_{pl}(C) \) cannot be zero. Thus we get a contradiction. Therefore Case 1 cannot occur.

**Case 2:** \( P_1 \) and \( P_2 \) have common intermediate vertices

7
Note that at any common intermediate vertex, the paths \( P_1 \) and \( P_2 \) can either cross each other or tangentially touch each other without crossing. We refer to the former as **crossing vertex** and the latter as **grazing vertex**.

We will show that the closed walk formed by \( P_1 \) and \( P_r \) reduces to a surface separating simple cycle such that the weight of the closed walk is almost equal to that of the cycle.

**Lemma 10.** Let \( P_1 \) and \( P_2 \) be two minimum weight paths from \( u \) to \( v \) with \( u_1, u_2, \ldots, u_l \) being the set of common intermediate vertices. Then \( u_1, u_2, \ldots, u_l \) must occur in the same order in both paths \( P_1 \) and \( P_2 \).

**Proof.** Lemma is trivially true when \( l = 1 \). So, let \( l > 1 \). Suppose \( u_i \) occurs before \( u_j \) in \( P_1 \) and \( u_j \) occurs before \( u_i \) in \( P_2 \), for \( i < j \). Let \( a, b \) and \( c \) be the lengths of path \( P_1 \) from \( u \) to \( u_i \), \( u_i \) to \( u_j \) and \( u_j \) to \( v \) respectively. Similarly, let \( d, e \) and \( f \) be the lengths of path \( P_2 \) from \( u \) to \( u_j \), \( u_j \) to \( u_i \) and \( u_i \) to \( v \) respectively. Since \( \text{len}(P_1) = \text{len}(P_2) \) we have

\[
a + b + c = d + e + f. \tag{1}
\]

If \( d < a + b \) then taking \( P_2 \) from \( u \) to \( u_j \) and \( P_1 \) from \( u_j \) to \( v \) gives us a shorter length path from \( u \) to \( v \) than either \( P_1 \) or \( P_2 \). Similarly, if \( d > a + b \) we can construct a shorter length from \( u \) to \( v \) as well. Hence we can assume that

\[
d = a + b. \tag{2}
\]

Using analogous argument we can assume

\[
f = b + c. \tag{3}
\]

Now adding Equations 2 and 3 we have

\[
a + 2b + c = d + f. \tag{4}
\]

Now since \( b \) and \( e \) are non zero, Equations 1 and 4 contradict each other. Hence \( u_1, u_2, \ldots, u_l \) occur in the same order in paths \( P_1 \) and \( P_2 \).

**Lemma 11.** Let \( P_1 \) and \( P_2 \) be two paths in \( K_{uv}^n \) having crossing vertices \( v_1, v_2, \ldots, v_k \), such that these vertices divide \( P_1 \) and \( P_2 \) into \( k + 1 \) sub-paths \( P_1^1, P_2^2, \ldots, P_{k+1} \) and \( P_1^2, P_2^2, \ldots, P_{k+1}^n \) respectively (as shown in Figure 3). Then the paths \( P' = P_1^1 P_2^2 \ldots P_{k+1}^1 \) and \( P'' = P_1^k P_2^k \ldots P_{k+1}^k \) (where \( i = 1 \) if \( k \) is even and \( i = 2 \) and \( j = 1 \) if \( k \) is odd) belong to the same class.

![Figure 3: Crossings of paths \( P_1 \) (bold line) and \( P_2 \) (dashed line) at \( k \) many points](image)

The intuition of Lemma 11 is that if \( P_1 \) and \( P_2 \) cross each other then the two paths obtained by taking the “above” and “below” portions of these two paths have the same signature.
Therefore by rearranging the terms we get

\[ \text{sign}(P_1) = \text{sign}(P_2) \]

\[ \text{sign}(P_1^1) \oplus \text{sign}(P_2^1) \oplus \ldots \oplus \text{sign}(P_1^{k+1}) = \text{sign}(P_2^1) \oplus \text{sign}(P_2^2) \oplus \ldots \oplus \text{sign}(P_2^{k+1}) \]

\[ \text{sign}(P') = \text{sign}(P'') \]

Hence \(P'\) and \(P''\) belong to the same class. \( \square \)

Note that \(P'\) and \(P''\) need not belong to the same class as \(P_1\) and \(P_2\). We define \(P_{i}^{j,k}(j < k)\) as a shorthand for path \(P_{i}^1, P_{i}^{j+1}, \ldots, P_{i}^{k} \).

**Lemma 12.** Let \(P_1\) and \(P_2\) are two minimum weight paths in \(K_{i}^{uv}\) having crossing vertices \(v_1, v_2, \ldots, v_{k}\), then \(w_{pl}(P_i) = w_{pl}(P_2)\), for all \(i, 1 \leq i \leq k + 1\). Additionally, for the closed walk \(C' = P'(P'')'\) we have that \(w_{pl}(C') = 0\) and \(\text{sign}(C') = 0\) (where \(P'\) and \(P''\) are as defined in Lemma 11).

**Proof.** Assume that there exists some \(j (1 \leq j \leq k + 1)\) such that \(j\) is the smallest index, where \(w_{pl}(P_{i}^{j}) \neq w_{pl}(P_{i}^{j})\). Without loss of generality assume that \(w_{pl}(P_{i}^{j}) < w_{pl}(P_{i}^{j+1})\). Now consider path \(\hat{P} = P_{i}^{j,j+1} P_{i}^{j+1,k+1}\). \(\hat{P}\) is a path from \(u\) to \(v\) and by construction \(w_{pl}(\hat{P}) < w_{pl}(P_2)\). This is a contradiction since \(P_2\) is a minimum weight path from \(u\) to \(v\). Therefore for all \(i\) we have \(w_{pl}(P_i^j) = w_{pl}(P_2^{j+1})\).

Now,

\[ w_{pl}(C') = w_{pl}(P') + w_{pl}((P'')') \]

\[ = w_{pl}(P_1^j) + w_{pl}(P_2^{j+1}) + \ldots + w_{pl}(P_1^{k+1}) + \]

\[ w_{pl}(P_{i}^{j+1}) + w_{pl}(P_{i}^{j+2}) + w_{pl}(P_{i}^{j+3}) + \ldots + w_{pl}(P_{i}^{k+1}) + \]

\[ = (w_{pl}(P_1^j) + w_{pl}(P_1^{j+1})) + (w_{pl}(P_2^{j+1}) + w_{pl}(P_2^{j+2})) + (w_{pl}(P_3^{j+1}) + w_{pl}(P_3^{j+2})) + \]

\[ \ldots + (w_{pl}(P_{i}^{j+1}) + w_{pl}(P_{i}^{j+2})) + (w_{pl}(P_{i}^{j+3}) + w_{pl}(P_{i}^{j+4})) + \]

\[ \ldots + (w_{pl}(P_{i}^{k+1}) - w_{pl}(P_{i}^{k+2})) + \]

\[ = 0. \]

By Lemma 11 we have that \(P'\) and \(P''\) belong to the same class. Hence \(\text{sign}(C') = \text{sign}(P') \oplus \text{sign}(P'') = 0\). \( \square \)

We now argue that there is a simple cycle (say \(\hat{C}\)) such that \(C'\) and \(\hat{C}\) are infinitesimally separated. Hence their signatures are the same. However the weight function \(w_{pl}\) depends on the coordinates of an edge, therefore \(w_{pl}(C')\) and \(w_{pl}(\hat{C})\) are nearly the same. This implies that \(w_{pl}(\hat{C})\) is close to zero. Which leads to a contradiction as we will show that \(|w_{pl}(\hat{C})| > |w_{pl}(\hat{C})|\) where \(\hat{C}\) is one of the planar cycles in which \(\hat{C}\) can be decomposed. Hence \(P_1\) and \(P_2\) cannot be two minimum weight paths in \(K_{i}^{uv}\).
Consider a graph \( \tilde{G} \) that is similar to \( G \) except that in \( \tilde{G} \) we split each common intermediate vertex \( u_1 \) (both crossing and grazing vertices) of the paths \( P_1 \) and \( P_2 \), into two vertices \( u'_1 \) and \( u''_1 \), such that \( u'_1 \) and \( u''_1 \) are \( \delta \) distance apart (see Figure 4). If \( e = xu_1 \) was an edge in \( P_1 \) (or \( P_2 \)) then we will have the edge \( e' = xu'_1 \) (or \( e' = xu''_1 \)) in \( \tilde{G} \). Let \( N = cn^k \) be an upper bound on the coordinates of the embedding of \( G \), where \( c \) and \( k \) are constants. Then by definition of \( w_{pl} \), we have \( |w_{pl}(e) - w_{pl}(e')| \leq 4N\delta + \delta^2 \). Let us define \( f(\delta) := 4N\delta + \delta^2 \).

Let \( v_1, v_2, \ldots, v_k \) be the crossing vertices of \( P_1 \) and \( P_2 \), and \( Q^{1'}, Q^{2'}, \ldots, Q^{(k+1)'} \) be the paths from \( u \) to \( v'_{1}, v'_{2} \) and so on till \( v'_{k} \) to \( v \) respectively, such that the paths \( Q^{1'}, Q^{2'}, \ldots, Q^{(k+1)'} \) correspond to the paths \( P^{1}_i, P^{2}_i, \ldots, P^{k+1}_i \) respectively (see Figure 4). Now since by Lemma 12 \( \text{sign}(Q^{1'}) = \text{sign}(P^{1}_i) \) so that we get \( |w_{pl}(P^{1}_i) - w_{pl}(Q^{1'})| \leq n \cdot f(\delta) \).

Similarly let \( Q^{1''}, Q^{2''}, \ldots, Q^{(k+1)''} \) be the paths from \( u \) to \( v''_1, v''_2 \) and so on till \( v''_k \) to \( v \) respectively, such that the paths \( Q^{1''}, Q^{2''}, \ldots, Q^{(k+1)''} \) correspond to the paths \( P^{2}_i, P^{3}_i, \ldots, P^{k+1}_i \) respectively. By an analogous argument we have \( |w_{pl}(P^{j}_i) - w_{pl}(Q^{(j+1)''})| \leq n \cdot f(\delta) \) (where \( j \) is 2 if \( i \) is odd and 1 otherwise).

![Figure 4: Splitting vertices to form the graph \( \tilde{G} \) from \( G \).](image)

Now \( Q' = Q^{1'} Q^{2'} \ldots Q^{(k+1)'} \) and \( Q'' = Q^{1''} Q^{2''} \ldots Q^{(k+1)''} \) are paths from \( u \) to \( v \) (corresponding to the paths \( P' \) and \( P'' \) respectively) that do not cross each other, as shown in Figure 4. Observe that \( \text{sign}(Q') = \text{sign}(P') \) since the difference between the coordinates of vertices along \( Q' \) and \( P' \) is less than 1, therefore the number of crossings with respect to each segment of the flat schema remains the same. Similarly, \( \text{sign}(Q'') = \text{sign}(P'') \). Now consider the simple cycle \( \hat{C} = Q'(Q'')^r \). By Lemma 12, \( \text{sign}(\hat{C}) = 0 \). Hence \( \hat{C} \) is a surface separating cycle by Theorem 3.

\[
|w_{pl}(\hat{C}) - w_{pl}(C')| = |(w_{pl}(Q') + w_{pl}(Q'')) - (w_{pl}(P') + w_{pl}(P''))| \\
= |\left(w_{pl}(Q^{1'}) + \ldots + w_{pl}(Q^{(k+1)'})\right) - \left(w_{pl}(Q^{1''}) + \ldots + w_{pl}(Q^{(k+1)''})\right)| \\
- \left|\left(w_{pl}(P^{1}_1) + \ldots + w_{pl}(P^{(k+1)1}_i)\right) - \left(w_{pl}(P^{2}_1) + \ldots + w_{pl}(P^{(k+1)1}_j)\right)\right| \\
\leq |w_{pl}(Q^{1'}) - w_{pl}(P^{1}_1)| + \ldots + |w_{pl}(Q^{(k+1)''}) - w_{pl}(P^{2}_j)| \\
\leq 2(k + 1)n f(\delta)
\]

Now since by Lemma 12 \( w_{pl}(C') = 0 \), therefore we can choose \( \delta \) small enough (say less than \( 1/100N^3 \)) so that we get \( |w_{pl}(\hat{C})| < 1/3 \).

Without loss of generality assume that \( C' \) crosses some segment of the flat schema. If not then both \( P_1 \) and \( P_2 \) would not be crossing any segment of the polygon and hence with respect
to \( w_{pl} \) both cannot be minimum weight paths [21]. Since \( C' \) crosses some segment, therefore, \( \hat{C} \) also must cross the same segment. Since \( \hat{C} \) is a surface separating cycle therefore by Lemma 8, \( \hat{C} \) can be decomposed into planar cycles such that the weight of \( \hat{C} \) is equal to sum of the weights of the planar cycles with respect to \( w_{pl} \). Moreover, the weight of each planar cycle has the same sign and each planar cycle has a dummy edge (an edge that is incident on a segment of the flat schema). Let \( \hat{C} \) be one such planar cycle, and consider a triangulation of \( \hat{C} \) (by thinking of \( \hat{C} \) as a polygon). There exists some triangle say \( T = (a,x,y) \) in this triangulation that contains the dummy edge \( xy \) of \( \hat{C} \) as one of its sides. Now \( ||x - y|| \geq 1 \) since vertices in \( C' \) were integral and in \( \hat{C} \), \( x \) and \( y \) were not shifted. Moreover, \( a \) cannot be a vertex that is \( \delta \) close to any segment of the flat schema. This is because for every vertex \( v \) that lies at the intersection of cycle \( C' \) and the side \( S \) of the flat schema, \( v \) was not split when forming the cycle \( \hat{C} \). Hence the distance of \( a \) from the line joining \( x \) and \( y \) is at least \( 1 - \delta \). Therefore the area of the triangle \( \text{Area}(T) > 1/2 - 1/200n \). Now, \( \text{Area}(T) \leq \text{Area}(\hat{C}) \leq |w_{pl}(\hat{C})| \leq |w_{pl}(\hat{C})| \leq 1/3 \), where the second inequality follows from Theorem 6. This contradicts that \( P_1 \) and \( P_2 \) are two minimum weight paths in \( G \) with respect to \( w_{comb} \).

Therefore the class \( K_{uw}^4 \) has at most one minimum weight path from \( u \) to \( v \) with respect to \( w_{comb} \). This completes the proof of Theorem 9.

For a fixed pair of vertices \( u, v \), the number of classes \( K_{uw}^4 \) is at most \( 2^{2g} \). Since by Theorem 9 there is at most one minimum weight path from \( u \) to \( v \) in each class \( K_{uw}^4 \), therefore we have the following result.

**Theorem 13.** Let \( G = (V, E) \) be a genus \( g \) graph embedded on a flat schema having \( 4g \) segments. Then there exists at most \( 2^{2g} \) minimum weight paths between any pair of vertices in \( G \), with respect to weight function \( w_{comb} \).

Now we are ready to prove Theorem 7 which says that there is a weight function with respect to which there is at most one minimum weight path between any pair of vertices in \( G \).

**Proof of Theorem 7.** Let \( M_{uw} \) be the set of all minimum weight paths from \( u \) to \( v \) and let \( M = \bigcup_{(u,v) \in V^2} M_{uw} \). By Theorem 13, \( |M_{uw}| \) is at most \( 2^{2g} \). Hence \( |M| \leq n^2 \cdot 2^{2g} \). Now by Theorem 4 there is an \( O(\log n + g) \) bit weight function \( w_{fks} \) which for some suitable prime \( p \) assigns the weight \( 2^i \mod p \) to the \( i \)th edge, such that every path in \( M \) gets a distinct weight with respect to \( w_{fks} \). Therefore with respect to the weight function \( w = w_{comb} \cdot n^{k_2} + w_{fks} \), where \( k_2 \) is a sufficiently large constant, the minimum weight path between every pair of vertices is unique. Note that \( w_{comb} \) and \( w_{fks} \) are \( O(\log n) \) bit and \( O(\log n + g) \) bit weight functions respectively.

Computing \( w_{comb} \) can be done in logspace since it is a simple function of the coordinates of the end points of an edge. To compute \( w_{fks} \) one needs to find the appropriate prime whose existence is shown in Theorem 4. For each prime, we check if \( G \) is min-unique with respect to the corresponding weight function and if not we move to the next prime. This can be done by a nondeterministic \( O(\log n + g) \) space algorithm along a unique computation path as shown in [15].

**Proof of Theorem 1.** Now given a graph \( G \) on \( n \) vertices and two vertices \( s \) and \( t \) in \( G \) we cycle through all primes less than \( n' \), and for each prime, we compute the weight function \( w \) given in Theorem 7. Using Theorem 5 we check if \( G \) is min-unique with respect to \( w \) and if so we check if there is a path from \( s \) to \( t \) in \( G \). If \( G \) is not min-unique with respect to \( w \) then we move to the next prime. Theorem 4 guarantees that there is an \( n' = n^{O(1)} \) and a prime less than \( n' \) such that \( G \) is min-unique with respect to the corresponding prime. Hence along a unique computation path, we finally have Yes or No answer depending on whether \( s \) is reachable from \( t \) or not respectively, while all other paths halt and reject.
